Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS) are the most serious hyperglycemic emergencies in patients with type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM). Although DKA and HHS are often discussed as separate entities, they represent points along a spectrum of hyperglycemic emergencies because of poorly controlled diabetes. Both are characterized by insulinopenia and severe hyperglycemia. However, clinically they differ only by the degree of dehydration and the severity of metabolic acidosis.[1-4] The overall mortality in children and adult subjects with DKA is reported to be less than 1%, but a mortality rate higher than 5% is reported in the elderly and in patients with concomitant life-threatening illnesses.[3,5-7] The rate is also high in less developed nations, with mortality rates reported at over 40%.[8-10] In more developed nations, mortality in patients with HHS is higher than in those with DKA and has been reported as being as high as 20%.[11-13] Successful treatment of both conditions requires early recognition and diagnosis, frequent monitoring, replacement of fluid and electrolyte deficits to restore circulatory volume and tissue perfusion, correction of hyperglycemia, and a careful search for the precipitating cause. This chapter reviews recent advances on the pathophysiology, epidemiology, diagnosis, clinical manifestations, management recommendations, and prevention of DKA and HHS.

DIABETIC KETOACIDOSIS

Epidemiology

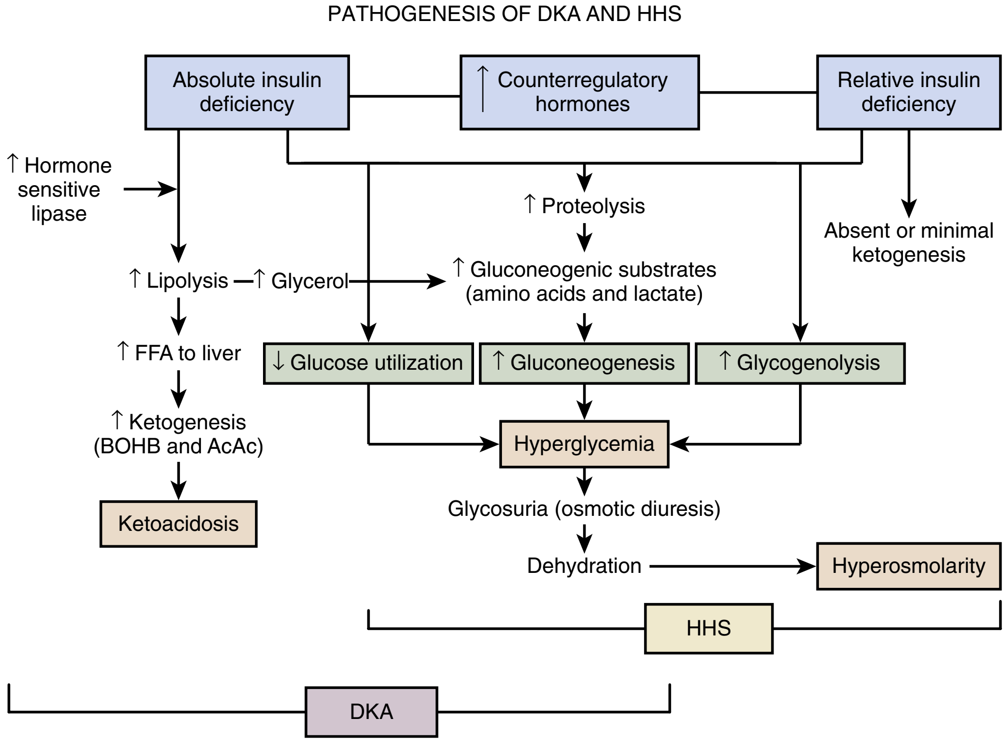
KEY POINTS

- DKA can occur in type 1 and type 2 diabetes and can occur at any age. Whilst it may be the presenting feature of new onset diabetes, this is uncommon, and most cases are in people with an existing diagnosis of diabetes.

DKA is the most common and serious acute complication of diabetes. DKA is responsible for more than 188,000 hospital admissions per year in the United States, at substantial cost related to direct medical expenses and indirect costs.[3,14-16] Recent epidemiological studies indicate that hospitalizations for DKA are increasing, with the majority of cases being recurrent cases in the same subjects.[17-21] Along with this, treatment of DKA uses many resources. In the United States an individual episode was estimated to cost $26,566, accounting for an estimated annual total cost in 2014 of over $5 billion.[15] In the United Kingdom the cost of an episode of DKA has been estimated at £2064 for adults and £1387 for children.[22,23]

Observational studies from the United States have reported that, in 2016, DKA accounted for 2.4% of all hospital admissions where diabetes was listed as a diagnosis (equal to a crude rate of 8.1 per 1000 people with diabetes).[24] Worldwide incidence rates are higher in populations with limited access to medical care for social or economic reasons. A systematic review of incidence around the world suggested a rate of 8.0 to 51.3 cases per 1000 people with T1DM, with the highest rates being in those aged between 15 and 39 years.[25] Data from China suggested the rates were higher, up to 263 per 1000 patient-years.[26] In the United States, the SEARCH for Diabetes in Youth Study found that, between 2002 and 2010, the rates of DKA as the presenting feature of T1DM amongst people younger than 20 years remained steady, at around 30%.[27] In addition, previous data from the same study showed that 29.4% of participants less than 20 years of age with type 1 diabetes presented with DKA, as compared with 9.7% of youth with T2DM.[28] In community-based studies, more than 40% of adult patients with DKA are older than 40 years, and more than 20% are older than 55 years.[29] Mortality increases with age and with the presence of comorbidities.[6,7] Patients with T2DM may develop DKA under stressful conditions such as trauma, surgery, or infection.[4,29] However, an increasing number of unprovoked ketoacidosis cases without precipitating cause have been reported in children and adult subjects with T2DM.[28] Unprovoked DKA cases are more commonly reported in African Americans and Latinos,[30-33] but have been reported in all ethnic groups.[34-37] A potentially helpful classification divides patients with DKA into four categories based on the presence or absence of biomarkers of autoimmunity (A+ or –) and the presence or absence of residual insulin secretory capacity as evidenced by C-peptide release (β+ or –).[38] Classic type 1 disease would be A+β–, while classic type 2 would be A–β+.[38,39]

In children and adult subjects with DKA, the overall mortality is less than 1%, but a mortality rate higher than 5% is reported in the elderly and in patients with concomitant life-threatening illnesses.[3]



PATHOGENESIS OF DKA AND HHS
Absolute insulin deficiency
↑ Counterregulatory hormones
Relative insulin deficiency
↑ Hormone sensitive lipase
↑ Proteolysis
Absent or minimal ketogenesis
↑ Lipolysis
↑ Glycerol
↑ Gluconeogenic substrates (amino acids and lactate)
↑ FFA to liver
↓ Glucose utilization
↑ Gluconeogenesis
↑ Glycogenolysis
↑ Ketogenesis (BOHB and AcAc)
Hyperglycemia
Ketoacidosis
Glycosuria (osmotic diuresis)
Dehydration
Hyperosmolarity
HHS
DKA

Fig. 37.1 **Pathogenesis of diabetic ketoacidosis.** Hyperglycemia and ketogenesis result from a relative or absolute insulin deficiency combined with excess levels of counterregulatory hormones including glucagon, cortisol, catecholamines, and growth hormone. Hyperglycemia develops as a result of increased gluconeogenesis, generation of gluconeogenic precursors (alanine, amino acids, and glycerol), accelerated glycogenolysis, and impaired glucose utilization by peripheral tissues. Accumulation of ketone bodies is caused by increased lipolysis and circulating free fatty acids (*FFAs*). In the liver, FFAs are oxidized to ketone bodies, a process predominantly stimulated by glucagon. The two major ketone bodies are β-hydroxybutyrate (*bOHB*) and acetoacetic acid (*AcAc*). Accumulation of ketone bodies leads to a decrease in serum bicarbonate concentration and metabolic acidosis. The ketosis and acidosis in diabetic ketoacidosis (*DKA*) contribute to electrolyte disturbances, vomiting and dehydration. *HHS,* Hyperglycemic hyperosmolar state.

In adult patients with diabetes, mortality increases substantially with age, with mortality rates for those over 65 to 75 years reaching 10% to 20%.[29] In the older age groups, the major cause of death relates to the underlying medical illness (i.e., trauma, infection) that precipitated the ketoacidosis, but in the younger patient, mortality is more likely to be because of the metabolic disarray.

Pathogenesis of Diabetic Ketoacidosis

The mechanisms that trigger DKA are multifactorial and include a combination of reduced secretion and action of insulin and raised levels of counterregulatory hormones (glucagon, catecholamines, cortisol, and growth hormone).[1,4,40] The insulin deficiency of DKA can be absolute in T1DM or relative as in T2DM in the presence of increased release in counterregulatory hormones that causes worsening of insulin resistance and further impairment of insulin secretion.[4,40,41]

Ketogenesis and Ketoacidosis. The combination of insulin deficiency and glucagon excess (elevated glucagon/insulin ratio) is critical for the development of hyperglycemia and ketoacidosis (see Chapters 30 and 36).[42] The increase in counterregulatory hormones leads to the release of free fatty acids (FFAs) into the circulation from adipose tissue (lipolysis) and to unrestrained hepatic fatty acid oxidation in the liver to ketone bodies (Fig. 37.1).[4,43,44] Insulin deficiency causes the activation of hormone-sensitive lipase in adipose tissue. The increased activity of tissue lipase causes breakdown of triglyceride into glycerol and FFAs. Although glycerol becomes an important substrate for gluconeogenesis in the liver, the massive release of FFAs assumes pathophysiologic predominance, as they are the hepatic precursors of the ketoacids. In the liver, FFAs are oxidized to ketone bodies, a process predominantly stimulated by glucagon-induced generation of cyclic adenosine monophosphate (cAMP). Increased concentration of glucagon lowers the hepatic levels of malonyl coenzyme A (CoA) by blocking the conversion of pyruvate to acetyl CoA through inhibition of acetyl CoA carboxylase, the first rate-limiting enzyme in *de novo* fatty acid synthesis. Malonyl CoA, inhibits carnitine palmitoyltransferase 1 (CPT-1), the rate-limiting enzyme for transesterification of fatty acyl CoA to fatty acyl carnitine,[45] allowing oxidation of fatty acid to ketone bodies. CPT-1 is required for movement of FFA into the mitochondria, where fatty acid oxidation takes place.[45] The increased fatty acyl CoA and CPT-1 activity in DKA lead to increased ketogenesis in DKA. Increased production ketone bodies (acetoacetate and β-hydroxybutyrate) lead to ketonemia and metabolic acidosis.[46,47]

Hyperglycemia. In normal subjects during fasting state, plasma glucose is maintained between 3.9 and 5.6 mmol/L (70 - 100 mg/dl) by a finely regulated balance between hepatic glucose production and glucose utilization in peripheral tissues (see Chapter 30). Insulin controls hepatic glucose production by suppressing hepatic gluconeogenesis and glycogenolysis. In insulin-sensitive tissues such as muscle, insulin promotes protein anabolism, glucose uptake, and glycogen synthesis and inhibits glycogenolysis and protein breakdown. In addition, insulin is a powerful inhibitor of lipolysis, FFA oxidation, and ketogenesis.

TABLE 37.1 **Diagnostic Criteria for Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar State**

DIAGNOSTIC CRITERIA AND CLASSIFICATION	DIABETIC KETOACIDOSIS			
	Mild	Moderate	Severe	Hyperglycemic Hyperosmolar State
Plasma glucose (mg/dL)	>250	>250	>250	>600
Arterial pH	7.25–7.30	7.00–≤7.24	<7.00	>7.30
Serum bicarbonate (mEq/L)	15–18	10–≤15	<10	>15
Urine ketone	Positive	Positive	Positive	Small
Serum ketone	Positive	Positive	Positive	Small
Effective serum osmolality	Variable	Variable	Variable	>320 mOsm/kg
Anion gap	>10	>12	>12	<12
Alteration in sensorium or mental obtundation	Alert	Alert/drowsy	Stupor/coma	Stupor/coma

The counterregulatory hormones (glucagon, catecholamines, cortisol, and growth hormone) promote metabolic pathways opposite to insulin action, both in the liver and peripheral tissues.[31]

Hyperglycemia in patients with DKA develops as a result of three processes: increased gluconeogenesis, accelerated glycogenolysis, and impaired glucose utilization by peripheral tissues (Fig. 37.1).[40] From a quantitative standpoint, increased hepatic glucose production represents the major pathogenic disturbance in DKA.[48] Renal gluconeogenesis also contributes approximately 20% of circulating glucose in healthy individuals, but a metabolic acidosis increases renal glucose output, while at the same time inhibiting hepatic glucose output.[49,50] The increased hepatic glucose production results from the high availability of gluconeogenic precursors, such as amino acids (alanine and glutamine, as a result of accelerated proteolysis and decreased protein synthesis), lactate (as a result of increased muscle glycogenolysis), and glycerol (as a result of increased lipolysis) and from the increased activity of gluconeogenic enzymes (phosphoenol pyruvate carboxykinase, fructose-1,6-bisphosphatase, and pyruvate carboxylase).[51,52] The activation of gluconeogenic enzymes appears to be predominantly stimulated by an increased synthesis of peroxisome proliferator-activated receptor γ-coactivator-1α mediated by glucagon-induced production of cAMP.[53,54] Elevation of cAMP also causes a fall in fructose 2,6-bisphosphate leading to inhibition of phosphofructokinase, a key regulatory enzyme in the glycolytic pathway.[55]

In addition to insulin deficiency, increased counterregulatory hormones play an important role in glucose overproduction in DKA. Elevated glucagon and catecholamine levels leads to increased gluconeogenesis and glycogenolysis.[56-58] Epinephrine stimulates glucagon secretion and inhibits insulin release by pancreatic β cells.[40,41] High cortisol levels stimulate protein catabolism and increase circulating amino acid concentrations, providing precursors for gluconeogenesis.[59,60] In addition, increased glucose levels causes an osmotic diuresis, which contributes to dehydration, hypovolemia, and decreased glomerular filtration rate, which further increase the severity of hyperglycemia.[4]

The development of hyperglycemia and ketoacidosis results in an inflammatory state characterized by an elevation of proinflammatory cytokines and increased oxidative stress markers.[61,62] Circulating levels of tumor necrosis factor-α (TNF-α), interleukin (IL)-6, IL-6β, IL-8, and C-reactive protein have been found to be increased 2- to 4-fold on admission in patients with hyperglycemic crises compared with control subjects, with levels returning to normal after insulin treatment and resolution of hyperglycemic crises.[62] The increased cytokine concentrations probably contribute to the insulin resistance associated with DKA through altered regulation of the insulin-signaling pathway and interaction at the level of the insulin receptor itself.[63] TNF-α causes a moderate decrease in the insulin-stimulated autophosphorylation of the insulin receptor and a dramatic decrease in tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1). Activation of c-Jun NH2-terminal kinase by TNF-α mediates serine phosphorylation of IRS-1, preventing insulin-mediated activation of phosphatidylinositol 3-kinase, a key regulator of tissue glucose uptake. Similarly, elevated fatty acids during DKA could stimulate phosphorylation of IRS-1 on its serine residues, leading to worsening insulin resistance.[64,65]

Increased oxidative stress and generation of reactive oxygen species during acute illness can lead to cellular damage of lipids, membranes, proteins, and DNA. Oxidative stress decreases the expression and activity of key transcription factors that regulate genes involved in β cell function. The increased inflammatory state in DKA can lead to capillary perturbation through activation of vasoactive peptides like endothelin 1, vascular endothelial growth factor, and intercellular adhesion molecule-1, whose expression levels are influenced by ketones bodies,[66,67] and may explain why hyperglycemia is associated with poor vascular outcomes in hyperglycemic patients.[61]

Precipitating Factors

DKA is the initial manifestation of diabetes in up to 20% of adult patients and in 30% to 40% of children with T1DM.[4,27] Recurrent episodes have been reported to occur in between 21.6% and 66% of people with either T1DM or T2DM.[18,68] In known diabetic patients, precipitating factors for DKA, particularly for recurrent episodes, include infections, intercurrent illnesses, psychological stress, and poor compliance with therapy.[68,69] Infection is the most common precipitating factor for DKA, occurring in 14% to 58% of cases (Table 37.1).[4] Urinary tract infection and pneumonia account for the majority of infections. Other acute conditions that may precipitate DKA include cerebrovascular accident, alcohol abuse, pancreatitis, pulmonary embolism, myocardial infarction, and trauma. Drugs that affect carbohydrate metabolism such as corticosteroids, thiazides, sympathomimetic agents, and pentamidine may also precipitate the development of DKA, as well as the use of the atypical antipsychotic agents.[6,70] The sodium-glucose cotransporter inhibitors, when used in people with T2DM, have been shown to be associated with an increased risk of developing DKA when compared to those not on these agents. US Food and Drug Administration data show that, among patients who met criteria for T2DM, DKA rates ranged from 0.32 (95% confidence interval [CI]: 0.26–0.40) for dapagliflozin to 0.44 (95% CI: 0.40–0.48) per 100 person-years for canagliflozin.[71] In people with T1DM, before the widespread use of these agents, the rate of DKA in the United Kingdom were reported at between 3.0% and 8.7% (depending on the definition of DKA used).[72] With the use of these agents in people with T1DM, in clinical trials the relative risk has risen to between 1.76- to 18.64-fold higher than with placebo.[73] The exception to this increased risk was the use of 2.5 mg of empagliflozin, which was associated with a 72% relative risk reduction in the incidence of DKA.[74]

Pregnant women with diabetes are also at higher risk compared with nonpregnant diabetic women. Risk factors that can predispose pregnant women include accelerated starvation, dehydration, nausea or hyperemesis gravidarum, decreased buffering capacity as a result of increased pulmonary ventilation and compensatory decrease in bicarbonate, stress, and increased production of human placental lactogen, prolactin, and cortisol.[75,76]

The importance of noncompliance and psychological factors in the incidence of DKA has been particularly apparent in younger patients. In adult patients with T1DM, poor adherence to diabetes treatment program is also the major precipitating cause of DKA.[4,6,70,77] Several behavioral, socioeconomic, and psychosocial factors contribute to poor treatment adherence. Psychiatric disorders such as depression, anxiety, and eating disorders are common among patients with T1DM, and the history of a psychiatric disorder can double the risk of having a DKA episode.[4,68,78] Studies have reported eating disorders in up to 20% of recurrent episodes of ketoacidosis in young women.[79]

Diagnosis of Diabetic Ketoacidosis

Symptoms and Signs. The clinical manifestations are polyuria, polydipsia, signs of dehydration, and progressive deterioration of mental status leading to coma. Abdominal pain, sometimes mimicking an acute abdomen, is reported in 40% to 75% of cases of DKA.[80] In addition, nausea and vomiting are commonly seen in DKA and are likely to be caused largely by the combined effects of dehydration, ketonemia, and delayed gastric emptying. The presence of abdominal pain is associated with more severe metabolic acidosis, but not with the severity of hyperglycemia.[80] The osmotic diuresis leads to a high urine output until extreme volume depletion leads to a critical decrease in renal blood flow and glomerular filtration.

Physical examination reveals signs of dehydration, including dry mucous membranes, tachycardia, and hypotension. Acetone on the breath and labored Kussmaul respiration characterized by rapid, deep respirations in response to metabolic acidosis are frequently found in children and adults with severe metabolic acidosis. Mental status can vary from full alertness to profound lethargy; however, less than 20% of patients are hospitalized with loss of consciousness.[40,81] Hypothermia, potentially owning to a failure of heat production as a result of impaired oxygen consumption, is not uncommon, and can potentially aggravate ketoacidosis.[82,83] The presence of fever is highly suggestive of a concomitant infection.

KEY POINTS

- DKA should only be diagnosed with glucose is >200mg/dl OR there is a known history of diabetes (the "D"), there is a ketonemia of >3.0mmol/l OR ketonuria of ≥2+ (the "K"), and a high anion gap metabolic acidosis with a pH of <7.3 or a bicarbonate of <18mmol/l (the "A").

Laboratory Findings. The syndrome of DKA consists of the triad of hyperglycemia (the "D"), ketonemia (the "K"), and metabolic acidosis (the "A").[3,84] DKA can be classified as mild, moderate, or severe, depending on the extent of metabolic acidosis and level of sensorium (Table 37.1).[3] The severity of metabolic acidosis often bears little relationship to the degree of hyperglycemia, and cases of ketoacidosis with normal or only modestly elevated glucose levels (<13.8 mmol/L, 250 mg/dL) have been reported.[72,85] This phenomenon has been reported during pregnancy, in patients with prolonged starvation, and in those who present after receiving insulin.[86] Similarly, relatively low glucose concentrations may occur in the presence of impaired hepatic glucose output, such as in patients with alcohol abuse or liver failure.[4,87,88]

The key diagnostic feature is the elevation in circulating total blood ketone concentration. Assessment of ketonemia is usually performed by the nitroprusside reaction, which provides a semiquantitative estimation of acetoacetate and acetone levels. Although the nitroprusside test (urine and serum) is highly sensitive, it can underestimate the severity of ketoacidosis, because this assay does not recognize the presence of β-hydroxybutyrate, the main metabolic product in ketoacidosis.[51,89] If available, measurement of serum β-hydroxybutyrate should be used for the diagnosis and monitoring of progress.[47,90] Previous work has shown that home capillary blood β-hydroxybutyrate testing is more effective than urine acetoacetate testing in reducing emergency visits, hospitalization, and time to recovery from DKA.[91,92] Bedside capillary β-hydroxybutyrate testing is advocated as one of the cornerstones of management in the UK DKA guidelines.[93]

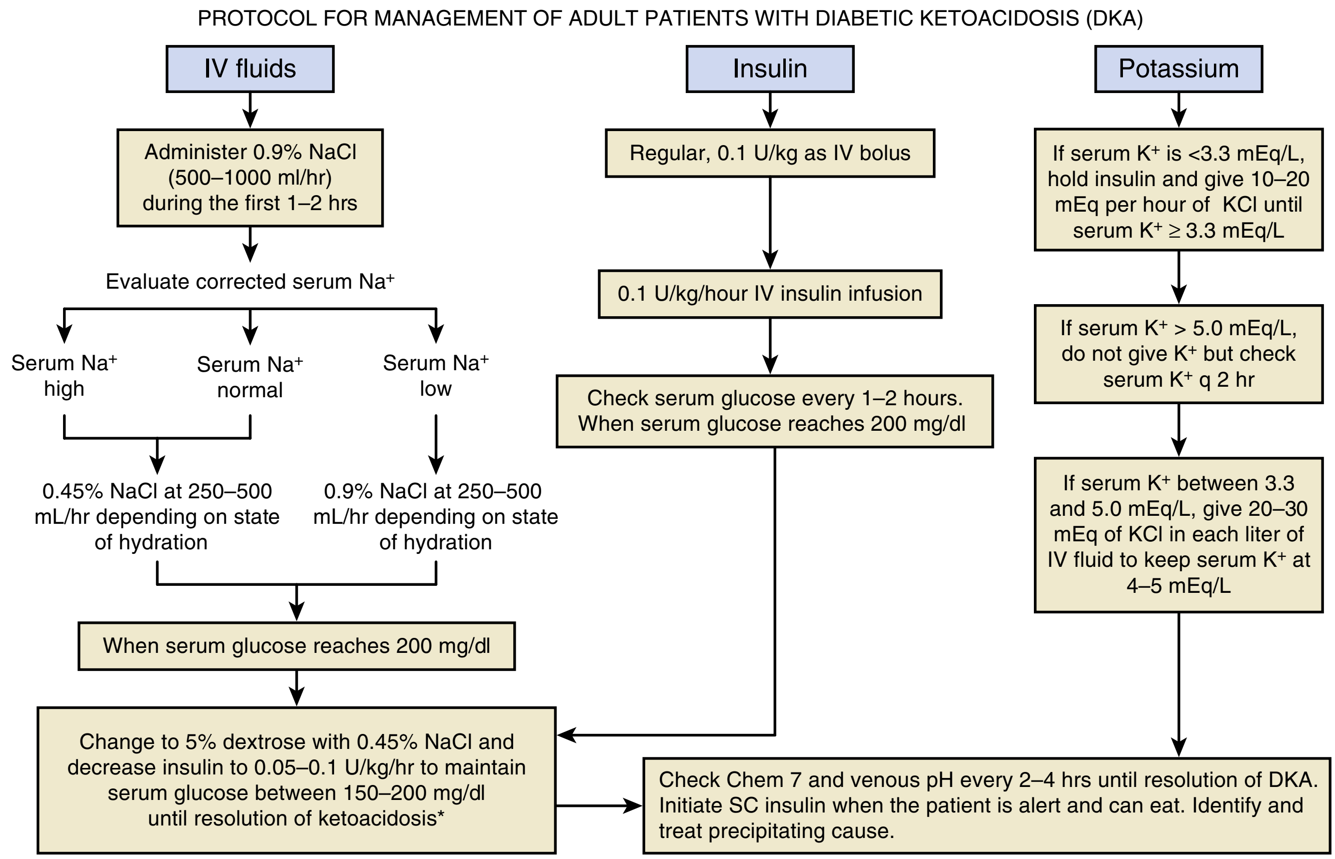
Accumulation of ketoacids results in an increased anion gap metabolic acidosis. The anion gap is calculated by subtracting the sum of chloride and bicarbonate concentration from the sodium concentration ($Na^+ - [Cl^- + HCO_3^-]$) (Fig. 37.2). A normal anion gap is between 7 and 9 mEq/L, and an anion gap greater than 12 mEq/L indicates the presence of increased anion gap metabolic acidosis.[40] Although most subjects with DKA present with a high anion gap acidosis, it is important to keep in mind that patients may present with mixed acid-base disorders.[94] More importantly, during treatment and resolution of DKA, most patients develop a transient hyperchloremic non–anion gap metabolic acidosis.[88,95]

Patients with DKA have an extracellular fluid volume deficit, usually in the range of 4% to 10%.[96-99] Clinical estimates of the volume deficit are subjective and inaccurate.[99-101] The magnitude of dehydration cannot be assessed accurately by either clinical or biochemical parameters. Calculation of effective osmolality [sodium ion (mEq/L) × 2 + glucose (mg/dL)/18] is the best marker of volume depletion, and levels greater than 320 mmol/L are frequently associated with impaired mental status (Table 37.2).

The admission serum sodium is often low because of the osmotic flux of water from the intracellular to the extracellular space in the presence of hyperglycemia. To assess the severity of sodium and water deficit, serum sodium may be corrected by adding 1.6 mg/dL to the measured serum sodium for each 100 mg/dL of glucose above 100 mg/dL (Table 37.2).[40] An increase in serum sodium concentration in the presence of hyperglycemia indicates a rather profound degree of water loss.

The admission serum potassium concentration is usually elevated in patients with DKA.[4,40] These high levels occur because of a shift of potassium from the intracellular to the extracellular space because of acidemia, insulin deficiency, and hypertonicity. In addition, as the circulating volume decreases owing to the hyperglycemia-induced osmotic diuresis, aldosterone concentrations rise in an attempt to retain sodium, but at the expense of further potassium losses. Similarly, the admission serum phosphate level may be normal or elevated because of metabolic acidosis.

Patients with DKA frequently present with leukocytosis in the absence of infection.[102] However, a leukocyte count greater than 25,000 per mm^3 or the presence of greater than 10% neutrophil bands is seldom seen in the absence of bacterial infection.[3] Because most patients with DKA present with abdominal pain, nausea, or vomiting, the differential diagnosis of acute pancreatitis should be considered.



PROTOCOL FOR MANAGEMENT OF ADULT PATIENTS WITH DIABETIC KETOACIDOSIS (DKA)
IV fluids
Insulin
Potassium
Administer 0.9% NaCl (500–1000 ml/hr) during the first 1–2 hrs
Evaluate corrected serum Na+
Serum Na+ high
Serum Na+ normal
Serum Na+ low
0.45% NaCl at 250–500 mL/hr depending on state of hydration
0.9% NaCl at 250–500 mL/hr depending on state of hydration
When serum glucose reaches 200 mg/dl
Change to 5% dextrose with 0.45% NaCl and decrease insulin to 0.05–0.1 U/kg/hr to maintain serum glucose between 150–200 mg/dl until resolution of ketoacidosis*
Regular, 0.1 U/kg as IV bolus
0.1 U/kg/hour IV insulin infusion
Check serum glucose every 1–2 hours. When serum glucose reaches 200 mg/dl
If serum K+ is <3.3 mEq/L, hold insulin and give 10–20 mEq per hour of KCl until serum K+ ≥ 3.3 mEq/L
If serum K+ > 5.0 mEq/L, do not give K+ but check serum K+ q 2 hr
If serum K+ between 3.3 and 5.0 mEq/L, give 20–30 mEq of KCl in each liter of IV fluid to keep serum K+ at 4–5 mEq/L
Check Chem 7 and venous pH every 2–4 hrs until resolution of DKA. Initiate SC insulin when the patient is alert and can eat. Identify and treat precipitating cause.

*Resolution of ketoacidosis = blood glucose < 250 mg/dl, bicarbonate > 18 mEq/L, and pH > 7.30.

Fig. 37.2 Protocol for management of patients with diabetic ketoacidosis (*DKA*). *IV,* Intravenous; *K+,* potassium ion; *KCl,* potassium chloride; *Na+,* sodium ion; *NaCl,* sodium chloride.

TABLE 37.2 Useful Formulas for the Evaluation of Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar State

1	Calculation of anion gap (AG): $\text{AG} = [\text{Na}^+] - [\text{Cl}^- + \text{HCO}_3^-]$
2	Total and effective serum osmolality: $\frac{\text{Total} = 2[\text{Na}^+] + \text{glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$
3	$\frac{\text{Effective} = 2[\text{Na}^+] + \text{glucose (mg/dL)}}{18}$
4	Corrected serum sodium: Corrected $[\text{Na}^+] = \frac{1.6 \times (\text{mg/dL}) - 100}{100} + [\text{measured Na}^+]$
	Total body water (TBW) deficit: TBW deficit $= [\text{weight (kg)} \times 0.6] - \frac{\text{corrected Na}^+ - 1}{140}$

BUN, Blood urea nitrogen.

Increased amylase levels are reported in 21% to 79% of patients with DKA. There is little correlation between the presence, degree, or isoenzyme type of hyperamylasemia and the presence of symptoms or pancreatic imaging studies; therefore, an increased serum amylase is not definitive for the diagnosis of pancreatitis in DKA.[80] Nonspecific serum lipase elevation has also been reported in one third of patients with DKA in the absence of clinical and radiological evidence of acute pancreatitis.[80] Even though the patient may present with features of an "acute abdomen," the DKA must be treated before any attempt at surgical intervention.

Not all patients who present with anion gap acidosis or ketoacidosis have DKA.[2] Patients with chronic ethanol abuse with a recent binge culminating in nausea, vomiting, and acute starvation may present with alcoholic ketoacidosis. The key diagnostic feature that differentiates diabetic and alcohol-induced ketoacidosis—in individuals not known to have diabetes—is the concentration of blood glucose.[88,103] Although DKA is characterized by severe hyperglycemia, the presence of ketoacidosis without hyperglycemia in an alcoholic patient is virtually diagnostic of alcoholic ketoacidosis. Of course, as mentioned, with the advent of sodium-glucose cotransporter inhibitor use, euglycemic DKA is within the differential diagnosis, and so (as with everything) taking a good history is paramount. Some patients with decreased food intake (<500 calories/day) for several days may present with starvation ketosis.[104] However, a healthy subject is able to adapt to prolonged fasting by increasing ketone clearance by peripheral tissue (brain and muscle) and by enhancing the kidney's ability to excrete ammonia to compensate for the increased acid production. In starvation, ketone concentrations rise slowly, reaching 5 to 6 mmol/L after a few days of absolute starvation or 4 to 5 mmol/L after 10 days.[105-107]

Treatment

KEY POINTS

- Whilst there is no true physiological replacement fluid for DKA, most people use 0.9% sodium chloride solution as the fluid of choice. Fluid replacement (with potassium supplementation) is paramount, followed by insulin. The routine use of bicarbonate, phosphate or magnesium replacement is discouraged.

Fig. 37.2 shows the American Diabetes Association (ADA) algorithm for the treatment of DKA.[3] The goals of DKA therapy are: (1) to improve circulatory volume and ultimately tissue perfusion, (2) to correct hyperglycemia by gradually decreasing serum glucose and plasma osmolarity, (3) to correct electrolyte imbalance and reduce serum ketone body concentrations, and (4) to identify and treat precipitating events. Frequent monitoring of vital signs, volume and rate of fluid administration, insulin dosage, and urine output and assessment of response to medical treatment are essential for the successful management of DKA. Serial laboratory measurements include glucose, electrolytes, venous pH, bicarbonate, and anion gap values until resolution of ketoacidosis.

There are recent data to show that guidelines used in treating DKA are safe and effective when treating adult patients with DKA in an intensive care unit (ICU) or in non-ICU settings.[5,108-112] Regular feedback given to healthcare staff also helps to further improve care.[113] Even though guidelines do have parameters to suggest when ICU teams should be involved, several observational and prospective studies have indicated no clear benefits in treating DKA patients in the ICU compared with step-down units or general medicine wards.[114-117] The mortality rate, length of hospital stay, or time to resolve ketoacidosis are similar between patients treated in ICU and non-ICU settings. In addition, ICU admission has been shown to be associated with more testing and significantly higher hospitalization cost in patients with DKA.[114,118] Thus, patients with mild to moderate DKA can be safely managed in the emergency department, in step-down units, or on general medical wards with only patients with severe DKA or those with a critical illness as precipitating cause (e.g., myocardial infarction, gastrointestinal bleeding, sepsis) be treated in the ICU.[3,119]

Fluid Therapy. Patients with DKA are volume depleted, with an estimated water deficit of approximately 100 mL/kg of body weight.[40] The water deficit can be estimated, based on corrected serum sodium concentration, using the following equation: water deficit = (0.6)(body weight in kilograms) × (1- [corrected sodium/140]).[40] The goal is to replace half the estimated water deficit over a period of 24 hours. Aggressive fluid therapy expands intravascular volume, restores renal perfusion, and improves insulin sensitivity by reducing circulating counterregulatory hormone concentrations. Isotonic saline (0.9% sodium chloride [NaCl]) at a rate of 500 to 1000 mL/hour during the first 1 to 2 hours is usually sufficient to restore blood pressure and renal perfusion. Subsequent choice and rate of fluid replacement depend on hemodynamics, the state of hydration, serum electrolyte levels, and urinary output. In general, 0.45% NaCl infused at 250 to 500 mL/hour is appropriate if the corrected serum sodium is normal or elevated; 0.9% NaCl at a similar rate is appropriate if corrected serum sodium is low (Fig. 37.2).[40] The protocol for a systematic review of the fluids used to treat DKA has recently been published.[120]

Once the plasma glucose is approximately 250 mg/dL, 5% or 10% dextrose should be added to replacement fluids to allow continued insulin administration until ketonemia is controlled, while at the same time avoiding hypoglycemia.[3] The administration of large amounts of isotonic saline, which contains a high content of chloride, can lead to hyperchloremic metabolic acidosis.[121] Preliminary studies with the use of Ringer's lactate solution have reported a reduction of hyperchloremic acidosis, but this approach has not been shown to improve outcome or to reduce hospital length of stay compared with saline administration.[121,122]

Insulin Therapy. Insulin administration is the cornerstone of DKA therapy. Insulin increases peripheral glucose utilization and decreases hepatic glucose production, as well as inhibiting the release of FFA from adipose tissue and decreasing ketogenesis. Randomized controlled studies in patients with DKA have shown that lower doses of insulin therapy, compared with the very high doses used decades ago, are effective regardless of the route of administration.[123-127] A common and effective practice (particularly when the intravenous [IV] infusion may be delayed) includes an initial IV bolus of regular insulin of 0.1 units/kg of body weight followed by a continuous infusion of regular insulin at a dose of 0.1 units/kg per hour.[3,93] Previous work has shown that the initial bolus is not necessary if the hourly insulin infusion rate is started at 0.14 U/kg body weight.[128] Once the serum glucose has declined to about 250 mg/dL, the insulin infusion rate should be reduced to 0.05 units/kg per hour. Thereafter, the rate of insulin administration may need to be adjusted to maintain glucose levels at approximately 200 mg/dL and continued until ketoacidosis is resolved.

A patient with uncomplicated DKA can be treated with subcutaneous rapid-acting insulin lispro or insulin aspart.[116,117] These studies showed that, after an initial subcutaneous dose of 0.2 to 0.3 U/kg, the administration of 0.1 or 0.2 units/kg every 1 or 2 hours, respectively, was as effective as the continuous infusion of regular insulin. This is done in the emergency room or in non-ICU wards if adequate personnel are available for frequent glucose monitoring. More recently, the advent of the SARS-CoV-2 (COVID-19) viral pandemic has meant that many people who present with DKA may also need insulin given—either subcutaneously if they have mild biochemical derangement, in situations of low resource availability, or when health systems are overwhelmed and infusion pumps to deliver IV insulin are not available.[129,130] Several examples of such protocols are available to download at www.covidindiabetes.org/.

Potassium. Patients with DKA have an estimated total potassium deficit of approximately 3 to 5 mEq/kg of body weight. Despite this deficit, most patients with DKA have a serum potassium level at or above the upper limits of normal.[3,5] These high levels occur because of a shift of potassium from the intracellular to the extracellular space because of acidemia, insulin deficiency, and hypertonicity. Both insulin therapy and correction of acidosis decrease potassium levels by stimulating cellular potassium uptake in peripheral tissues and by increasing urinary excretion owing to high aldosterone concentrations. IV potassium should be initiated when serum concentration is below 5.0 mEq/L. The treatment goal is to maintain serum potassium levels within the normal range of 4 to 5 mEq/L.[3,93] Generally, 20 to 30 mEq of potassium chloride in each liter of infusion fluid is sufficient to maintain a potassium concentration within the normal range. Despite widespread use of protocols with an aggressive potassium replacement regimen, hypokalemia still occurs.[5,94] This raises the argument that insulin infusion rates may need to drop to 0.05 U/kg per hour once glucose concentrations drop. To prevent severe hypokalemia and risk of cardiac arrhythmias, patients with a serum potassium lower than 3.3 mEq/L should receive potassium replacement at a rate of 10 to 20 mEq per hour, with the insulin infusion delayed until potassium is 3 mEq/L or higher.

Bicarbonate. Several studies have evaluated the effect of alkalinization in patients with DKA and reported no advantage of bicarbonate therapy in improving cardiac and neurologic functions or in the rate of recovery of hyperglycemia and ketoacidosis.[131-139] Moreover, bicarbonate therapy can lead to higher risk of hypokalemia, decreased tissue oxygen uptake, and cerebral edema.[3] However, because severe acidosis may result in impaired myocardial contractility, cerebral vasodilatation, and coma, treatment guidelines recommend that, in patients with severe metabolic acidosis (pH <6.9), 50 to 100 mmol of sodium bicarbonate should be given as isotonic solution (in 200 mL of water) every 2 hours until pH rises to approximately 6.9 to 7.0. In patients with arterial pH greater than or equal to 7.0, no bicarbonate therapy is necessary.

Phosphate and Magnesium. Severe hypophosphatemia may lead to rhabdomyolysis, hemolytic uremia, and muscle weakness; however, several studies have failed to show any beneficial effect of phosphate replacement on clinical outcome. Furthermore, aggressive phosphate therapy is potentially hazardous, as indicated in case reports of children with DKA who developed hypocalcemia and seizures secondary to IV phosphate administration. Phosphate replacement should be reserved for patients cardiac dysfunction, anemia, respiratory depression, and a serum concentration lower than 1.0 to 1.5 mg/dL.[3]

Patients with DKA frequently have large magnesium deficits, but there are no data to determine whether replacement of magnesium is beneficial in improving clinical outcome. Replacement of magnesium should be considered in the occasional patient with severe hypomagnesemia and hypocalcemia. The recommended dose is 25 to 50 mg/kg for two to four doses given every 4 to 6 hours, with a maximum infusion rate of 2 g per hour.

Transition to Subcutaneous Insulin. IV insulin therapy should continue until the hyperglycemic crisis has resolved and the patient is eating and drinking. Criteria for resolution of DKA include a blood glucose lower than 200 mg/dL (11.1 mmol/L), a serum bicarbonate level equal to or greater than 18 mEq/L, and a venous pH greater than 7.3.[3] When this occurs, subcutaneous insulin therapy can be started.

It is important to recognize that the half-life of IV insulin is approximately 5 to 7 minutes; therefore, if insulin infusion is interrupted suddenly, the insulin concentration in blood could reach undetectable levels, with relapse of the hyperglycemia and ketoacidosis. Therefore, insulin infusion should be continued for 2 to 4 hours after subcutaneous insulin is started. Previous work showed that basal insulin given a few hours after starting insulin infusion facilitates treatment and prevents rebound hyperglycemia after discontinuation of IV insulin therapy.[140]

The best time to transition to subcutaneous insulin is once the patient is alert and able to take food by mouth. Patients previously treated with insulin can resume their previous regimen. Insulin-naïve adult patients can be started on 0.5 to 0.7 U/kg/day, in divided doses, to achieve adequate glucose control.[3,141] A basal prandial approach with insulin basal (e.g., glargine detemir, or degludec) and rapid-insulin (lispro, aspart, glulisine) analogs is the preferred treatment regimen after resolution of DKA. An alternative is the use of split-mixed insulin regimen with neutral protamine Hagedorn (NPH) and regular insulin twice daily or a multidose regimen of short- or rapid-acting and intermediate- or long-acting insulins.[3,141] A previous study compared the safety and efficacy of insulin analogs and human insulin during the transition from IV to subcutaneous insulin in patients with DKA. There were no differences in mean daily glucose levels, but 41% patients treated with NPH and regular insulin experienced one or more hypoglycemic events, compared with 15% of patients treated with insulin analogs. Thus, a basal bolus regimen with insulin analogs is safer and should be preferred over NPH and regular insulin following the resolution of DKA.[142]

Complications of Therapy

The two most common complications associated with the treatment of DKA in adult subjects are hypoglycemia and hypokalemia. Hypoglycemia is reported in 10% to 25% of patients during insulin therapy. Hypoglycemia is reported in 10% to 30% of patients with DKA, with the majority of hypoglycemic events occurring after several hours of insulin infusion (between 8 and 16 hours) or during the transition phase.[5] Failure to reduce the insulin infusion rate or to use dextrose-containing solutions when glucose levels reach 250 mg/dL are the two most common causes of hypoglycemia during insulin therapy. Frequent blood glucose monitoring during insulin infusion (every 1–2 hours) is mandatory to recognize hypoglycemia, because many patients with DKA do not experience adrenergic manifestations of sweating, nervousness, hunger, or tachycardia.

Other complications of diabetes include hyperchloremic acidosis with an excessive use of NaCl or potassium chloride, resulting in a nonanion gap metabolic acidosis. This acidosis has no adverse clinical effects and is gradually corrected over the subsequent 24 to 48 hours by enhanced renal acid excretion.[143] The development of hyperchloremia can be prevented with reduction of the chloride load by judicious use of hydration solutions.[40]

Cerebral edema is the most serious complication in children and has been reported in two studies to occur in approximately 1% or 0.3% to 0.9% of DKA episodes in children, respectively[144,145]; however, it is seldom reported in adult patients with DKA.[146] It is a serious complication in children, with a reported mortality of approximately 20% and permanent neurological morbidity. Symptoms and signs of cerebral edema are variable and include onset of headache, gradual deterioration in level of consciousness, seizures, sphincter incontinence, pupillary changes, papilledema, bradycardia, elevation in blood pressure, and respiratory arrest. Cerebral edema typically occurs 4 to 12 hours after treatment is activated, but it can be present before treatment has begun or may develop any time during treatment for DKA.[144] Although no single factor has been identified that can be used to predict the development of cerebral edema, a number of mechanisms have been proposed, including the role of cerebral ischemia and hypoxia, the generation of various inflammatory mediators, increased cerebral blood flow, disruption of cell membrane ion transport, and rapid shift in extracellular and intracellular fluids resulting in changes in osmolality. A large randomized controlled trial assessing 1389 episodes of DKA in 1255 children compared the use of rapid versus slow administration of either 0.9% or 0.45% NaCl solution. No differences in the rates of cerebral injury were seen, suggesting that the development of this complication may be idiosyncratic.[147]

Rhabdomyolysis may occur in patients with DKA, and more commonly with HHS, resulting in acute kidney failure, severe hyperkalemia, hypocalcemia, and muscle swelling causing compartment syndrome. The classic symptom triad of rhabdomyolysis includes myalgia, weakness, and dark urine, and monitoring creatine kinase concentrations every 2 to 3 hours is recommended for early detection.[148] In pediatric patients, rhabdomyolysis has been associated with a malignant hyperthermia–like syndrome that is not well understood.[149,150]

Prevention

KEY POINTS

- Education on 'sick day rules' and the provision of blood glucose and ketone testing equipment remain the most important interventions in preventing admission.

The most common precipitating causes of DKA include infection, intercurrent illness, psychological stress, and noncompliance with therapy. With improved outpatient treatment programs and better adherence to self-care, approximately 50% to 75% of DKA admissions may be preventable. In addition, provision of "sick day rules" can help when individuals are unwell. These state that insulin must never be stopped, even if the patient is not eating or drinking, and that frequent small sips of fluids should be continued to maintain hydration. Home capillary glucose should be done every 2 to 3 hours, and urine or capillary ketone measurements every few hours. Correction doses of insulin may be required. Outpatient management is more cost effective and can minimize missed days of school and work for patients with diabetes and their family members. The frequency of hospitalizations for DKA has been reduced following diabetes education programs, improved follow-up care, and access to medical advice from diabetes nurses or educators.[151] Many patients with recurrent DKA are unaware of sick-day management or the consequences of skipping or discontinuing insulin therapy.[152] It has been shown that quarterly visits to the endocrine clinic will reduce the number of emergency department admissions for DKA. An important feature of patient education is how to deal with illness. This includes: (1) communicating the importance of insulin therapy during illness and emphasizing that insulin should never be discontinued, (2) early contact with healthcare providers, (3) initiation of early management of fevers and infections, and (4) adequate fluid intake.[40] Diabetes education and sick-day management should be reviewed periodically in patients with T1DM and should include specific information on when to contact the healthcare provider, use of supplemental short- or rapid-acting insulin during illness, and, most importantly, the importance of never discontinuing insulin. If available, patients with T1DM should be instructed on the use of home blood ketone monitoring during illness and persistent hyperglycemia, which may allow for early recognition of impending ketoacidosis. β-hydroxybutyrate testing (capillary blood test) seems to be more effective than urine acetoacetate testing in reducing emergency department visits and hospitalizations.[47,92]

HYPERGLYCEMIC HYPEROSMOLAR STATE

Epidemiology

KEY POINTS

- HHS has a higher mortality rate that DKA because it most often occurs in an elderly population who have more co-morbidities. It is most frequent in Type 2 diabetes, but can occur in type 1 diabetes.

The term "hyperglycemic hyperosmolar state" was first coined in 1994.[1] This condition had previously been called several other things, including hyperglycemic hyperosmolar nonketotic coma and hyperosmolar nonacidotic diabetes. HHS is a serious and potentially lethal acute complication of diabetes.[94,153] The different forms of coma associated with diabetes were first described in 1886, with the distinction being made between the coma that comes on quickly, and all of the features of DKA, and the other associated with people who were overweight in whom symptoms came on slowly.[154] However, the importance of hypersomolality as an essential component of the syndrome was not recognized until the late 1950s.[155,156] Mortality in patients with HHS has decreased in recent decades, but remains higher than in DKA.[9,12,81,157-163] Previous work has reported a mortality rate of up to 20%.[11-13] An increased number of pediatric cases are being diagnosed, with a mortality rate as high as 37%.[164,165] Furthermore, HHS is not limited to people with T2DM. Data from a large European diabetes register showed that 31.6% of cases of HHS occurred in people with T1DM.[166]

Pathophysiology

KEY POINTS

- Infection, intercurrent illness, psychological factors and intentional or unintentional lack of compliance remain the most common precipitating factors for HHS. Other causes include drugs affecting carbohydrate metabolism and antipsychotic agents.

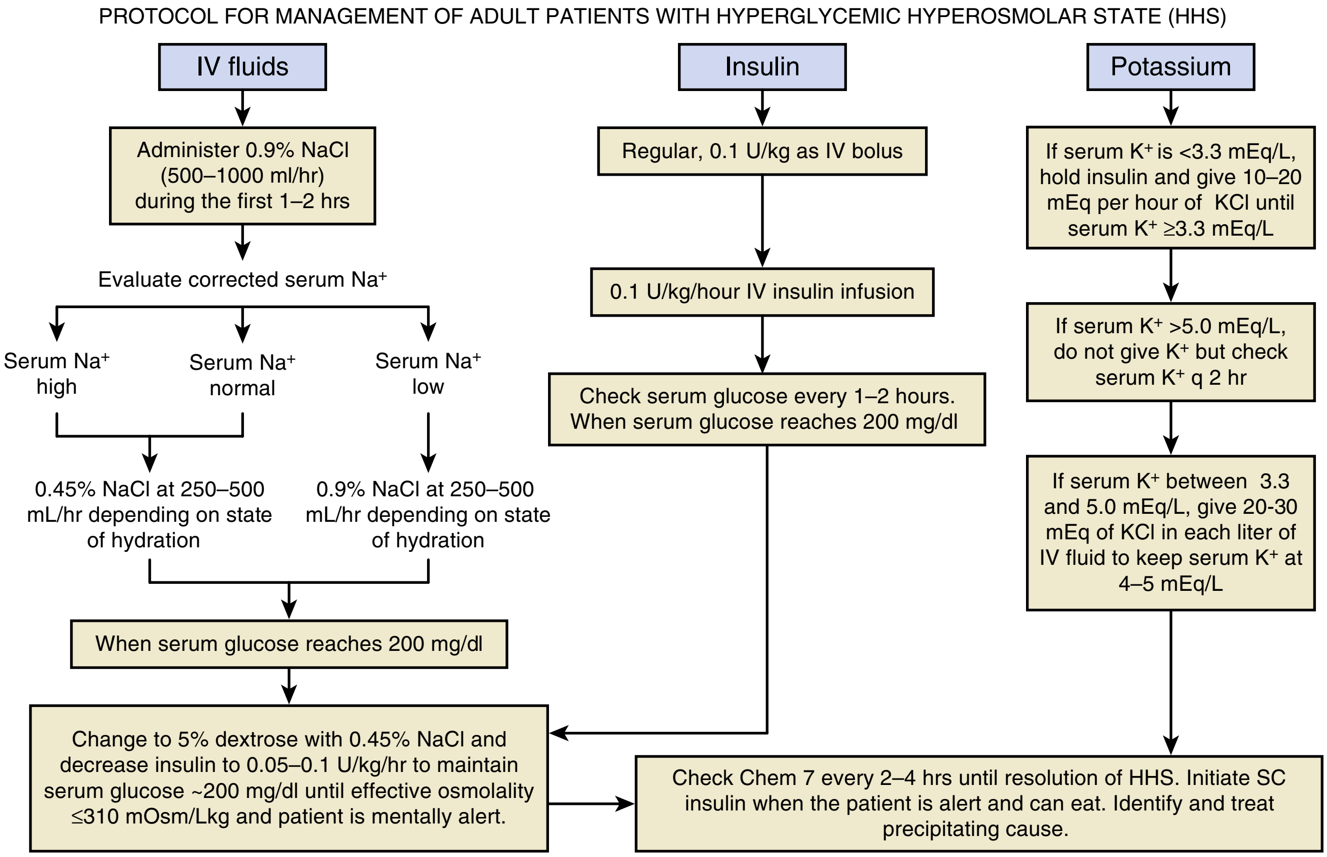
The pathophysiology of HHS is similar to that reported in DKA. Relative insulin deficiency and increased counterregulatory hormone concentrations leads to increase gluconeogenesis and decreased glucose uptake in peripheral tissues. The long duration and severity of hyperglycemia in HHS result in severe dehydration, hyperosmolality, and impaired renal function, which in turn lead to decreased excretion of glucose. It is speculated that higher levels of circulating insulin and lower levels of counterregulatory hormones in patients with HHS can explain the absent or minimal ketosis, which is the key difference from DKA. In general, three major mechanisms have been proposed for the lack of ketoacidosis in HHS: (1) higher levels of endogenous insulin in HHS (i.e., adequate insulin concentration to prevent lipolysis but inadequate to inhibit hepatic glucose production and/or stimulate glucose use), (2) lower levels of counterregulatory hormones and FFAs, and (3) inhibition of lipolysis by the hyperosmolar state, thereby decreasing ketogenesis.[1,40,158,167-169] However, HHS and DKA can occur in a mixed picture, with 27% of people presenting with a hyperglycemic emergency in one study having features of both at presentation.[94] Mortality was significantly high in this group, at 8% versus 3% for those with DKA and 5% for those with HHS ($P = .003$).[94]

Precipitating Events

KEY POINTS

- Infection, intercurrent illness, psychological factors and intentional or unintentional lack of compliance remain the most common precipitating factors for DKA. Other causes include drugs affecting carbohydrate metabolism and antipsychotic agents.

HHS occurs most commonly in older subjects with T2DM, but may be seen in younger and T1DM patients as well.[170] Up to 20% of patients admitted with HHS do not have a previous diagnosis of diabetes.[81] The most common precipitating causes are pneumonia and urinary tract infection, accounting for 30% to 50% of cases.[160,171,172] Other acute medical illnesses as precipitating causes include acute coronary syndromes, trauma, surgery, and cerebrovascular accident that provoke the release of counterregulatory hormones and/or compromise access to water. Certain medications that cause DKA may also precipitate the development of HHS, including glucocorticoids, thiazide diuretics, phenytoin, and β-blockers.[173] During the last few years, several case reports and retrospective studies have suggested an increased risk of developing diabetes mellitus in patients treated with atypical antipsychotics compared with schizophrenic patients treated with conventional antipsychotics or those without treatment.[174-178] Most cases of hyperglycemic crises associated with antipsychotics have been reported during treatment with clozapine and olanzapine.[179-181]



PROTOCOL FOR MANAGEMENT OF ADULT PATIENTS WITH HYPERGLYCEMIC HYPEROSMOLAR STATE (HHS)
IV fluids
Insulin
Potassium
Administer 0.9% NaCl (500–1000 ml/hr) during the first 1–2 hrs
Regular, 0.1 U/kg as IV bolus
If serum K^+ is <3.3 mEq/L, hold insulin and give 10–20 mEq per hour of KCl until serum K^+ ≥3.3 mEq/L
Evaluate corrected serum Na^+
0.1 U/kg/hour IV insulin infusion
If serum K^+ >5.0 mEq/L, do not give K^+ but check serum K^+ q 2 hr
Serum Na^+ high
Serum Na^+ normal
Serum Na^+ low
Check serum glucose every 1–2 hours. When serum glucose reaches 200 mg/dl
0.45% NaCl at 250–500 mL/hr depending on state of hydration
0.9% NaCl at 250–500 mL/hr depending on state of hydration
If serum K^+ between 3.3 and 5.0 mEq/L, give 20-30 mEq of KCl in each liter of IV fluid to keep serum K^+ at 4–5 mEq/L
When serum glucose reaches 200 mg/dl
Change to 5% dextrose with 0.45% NaCl and decrease insulin to 0.05–0.1 U/kg/hr to maintain serum glucose ~200 mg/dl until effective osmolality ≤310 mOsm/Lkg and patient is mentally alert.
Check Chem 7 every 2–4 hrs until resolution of HHS. Initiate SC insulin when the patient is alert and can eat. Identify and treat precipitating cause.

*Resolution of HHS = serum glucose < 250 mg/dl and effective plasma osmolality < 310 mOsm/kg

Fig. 37.3 Protocol for management of patients with hyperglycemic hyperosmolar state (*HHS*). *IV,* Intravenous; *K+*, potassium ion; *KCl*, potassium chloride; *Na+*, sodium ion; *NaCl*, sodium chloride; *SC,* subcutaneous.

Diagnosis

Symptoms and Signs. Although it is felt that the typical patient with HHS has undiagnosed diabetes, is between 55 and 70 years of age, and is frequently a nursing home resident, more recent data have suggested that there are few differences with respect to age and gender when compared with people presenting with DKA.[166] Indeed, approximately 1 in 230 people with T1DM presented with HHS in this large cohort.[166] However, most patients who develop HHS do so over days to weeks, during which they experience polyuria, dehydration, and progressive decline in the level of consciousness. Physical examination reveals signs of volume depletion. Fever because of underlying infection is common, and signs of acidosis (Kussmaul respiration, acetone breath) are usually absent. Gastrointestinal manifestations (abdominal pain, vomiting) frequently reported in patients with DKA are not part of HHS; thus, the presence of abdominal pain in patients without significant metabolic acidosis needs to be investigated.[80] In some patients, focal neurologic signs (hemiparesis, hemianopsia) and seizures (partial motor seizures more common than generalized) may be the dominant clinical features, resulting in a common misdiagnosis of stroke. Despite the focal nature of neurological findings, the neurologic manifestations often reverse completely after correction of the metabolic disorder. Neurologic symptoms of encephalopathy are commonly seen when serum sodium levels are in excess of 160 mEq/L or with calculated total and effective osmolalities higher than 340 and 320 mOsm/kg H_2O, respectively.

KEY POINTS

- HHS should be diagnosed when the glucose concentrations are >600mg/dl, without significant ketonuria or ketonemia, and no acidosis (pH>7.3). The calculated osmolality should be >320 mOsmol/Kg. The combination of HHS and DKA often occur together.

Laboratory Findings. The initial diagnostic criteria were reported by Gerich[158] and Arieff and Carroll[182] and included a blood glucose concentration greater than 600 mg/dL, a serum osmolality greater than 350 mOsm/L, and a serum acetone reaction no greater than 2+. In the original case series by Gerich[158] and Arieff and Carroll,[182] the mean plasma osmolarity in comatose patients was approximately 380 mOsml/L compared with approximately 320 to 330 mOsm/L in conscious subjects.[158,182,183] The importance of increased serum osmolality in the clinical presentation and prognosis of patients with HHS is well established. Altered sensorium (lethargy, stupor, coma) correlates better with hyperosmolality than with patient's age or severity of acid-base disturbance. The original formula to calculate serum osmolarity was Sosm = 2 [sodium (mEq/L)] + glucose (mg/dL)/18 + blood urea nitrogen (mg/dL)/2.8). In recent years, the total serum osmolality formula has been replaced by "effective" serum osmolality (Table 37.2).[40]

The ADA position statement diagnostic criteria for HHS are a plasma glucose concentration greater than 600 mg/dL, a serum osmolality greater than 320 mOsm/kg, and the absence of ketoacidosis[3] (Table 37.1). The UK definition is very similar.[184] Although by definition patients with HHS have a serum pH greater than 7.3, a serum bicarbonate greater than 18 mEq/L, and negative ketone bodies in urine and plasma, mild ketonemia may be present. Approximately 50% of patients with HHS have an increased anion gap metabolic acidosis as the result of concomitant ketoacidosis and/or an increase in serum lactate levels.[94]

Treatment

KEY POINTS

- Fluid replacement is the mainstay of treatment. Insulin should only be introduced once the glucose has stopped falling with fluids alone, to prevent rapid changes in osmolality.

At the same time as treating any underlying precipitating condition, the therapeutic measures for HHS are similar to those recommended for patients with DKA (Fig. 37.3). In general, the treatment of HHS should be directed at replacing volume deficit, correcting hyperosmolality and electrolyte disturbances, and managing the underlying illness that may have precipitated metabolic decompensation.[3,184] Patients with HHS may be severely dehydrated, with an average fluid deficit of 8 to 10 liters. Aggressive fluid replacement with normal saline at a rate of 1000 mL/hour for the first 2 to 3 hours is the usual recommendation, followed by 0.45% saline at a rate of 200 to 500 mL/hour. Insulin treatment does not need to be aggressive if fluid replacement is vigorously pursued. The UK guideline suggests that insulin should only be started once glucose concentrations have stopped falling with fluid resuscitation and then be started at 0.05 U/kg/hour.[184] This is different from the ADA guideline, which suggests that insulin be administered by an initial bolus of 0.1 U/kg followed by a continuous IV infusion calculated to deliver 0.1 U/kg/hour and continued at this rate until blood glucose has decreased to approximately 250 to 300 mg/dL. At this time, IV fluids should be changed to dextrose-containing solutions (5% dextrose), and the insulin dose should be decreased by 50% (0.05 U/kg/hour), or to 2 to 3 U/hour. Thereafter, the rate of insulin administration is adjusted to maintain a blood glucose level of approximately 200 mg/dL. Using this protocol, it has been reported that the mean duration of treatment in HHS for serum glucose levels to decrease into target range is approximately 11 hours.[81]

IV insulin infusion is usually continued until the patient is hemodynamically stable, the level of consciousness is improved, and the patient is able to tolerate food intake. Although most patients require insulin therapy after recovery from HHS, some patients could be managed with diet alone and/or diet plus an oral hypoglycemic agent during the initial admission or shortly after presentation.[1,185]

Increased serum potassium is commonly found in patients with HHS despite severe total body potassium depletion. Hyperglycemia and hyperosmolality cause a shift of potassium from the intracellular compartment into plasma and may contribute to a false estimate of total body potassium.[1,185] The serum potassium deficit in patients with HHS is estimated to be approximately 3 to 5 mEq/L of body weight.[1,185] The principles of potassium replacement in HHS are the same as in DKA. We recommend that potassium replacement be initiated after serum levels fall below 5.5 mEq/L, with the goal of maintaining a serum potassium concentration within the normal range of 4 to 5 mEq/L.

Complications

Venous thromboembolic events: Arterial and venous thrombosis have been described in patients with HHS.[186] Patients with T2DM are hypercoagulable compared with normal subjects.[187] However, uncomplicated diabetes is not an independent risk factor for incident venous thromboembolism (VTE).[188] The risk of thromboembolic events is higher in patients with HHS.[12,182,186,189-191] In a retrospective review of 426,831 cases of VTE, the overall incidence of thromboembolism among patients with hyperosmolarity was 1.7%.[189] Severe dehydration, along with hyperviscosity and hypotension, may predispose to intravascular clotting, and heparinization during the initial phase of treatment has been considered by some authors.[153,186,192] However, this has not been evaluated prospectively.

Rhabdomyolysis: Hyperosmolality alone could itself be a risk factor for rhabdomyolysis.[193,194] In 1981 Rumpf et al. described the association of acute rhabdomyolysis with myoglobinuric renal failure in a patient with HHS.[195] Since then it has been reported in adult and pediatric patients.[150] Subclinical rhabdomyolysis appears to be a common finding in HHS, and there seems to be a linear relationship between serum osmolarity, serum sodium, and the level of creatine kinase increase.[196] Rhabdomyolysis is a potentially life-threatening complication associated with acute kidney failure, multiorgan failure, severe hyperkalemia, and hypocalcemia leading to cardiac arrest, as well as muscle swelling causing compartment syndrome.[149,197]

Prevention

The most common precipitating causes of HHS are infection and intercurrent illness. Improved outpatient education and treatment programs, home capillary glucose monitoring, and better adherence to self-care should result in reduced admission of patients with hyperglycemic crises.

HYPOGLYCEMIA

Hypoglycemia, a condition of low plasma glucose, has many varied causes, which are discussed in the following sections. Hypoglycemia is uncommon in individuals without a diagnosis of diabetes. This chapter will review the pathophysiology of hypoglycemia, the defense mechanisms to safeguard against a low blood glucose, and the etiologies of hypoglycemia in the individual with and without diabetes (Table 38.1).

The definition of hypoglycemia is often debated, but in this chapter, the glucose values adopted by the Steering Committee[1] of the major stakeholders in international diabetes care will be used. Level 1 hypoglycemia is defined as a plasma glucose below 70 mg/dL (3.9 mmol/L) but greater than or equal to 54 mg/dL (3.0 mmol/L). Level 2 hypoglycemia is a plasma glucose less than 54 mg/dL (3.0 mmol/L), and level 3 hypoglycemia is a severe hypoglycemic event associated with significant neurologic deficits requiring assistance from a third party.

Accurate Measurement of Blood or Plasma Glucose

Before a thorough workup for possible hypoglycemia, certain nuances should be considered. Whole blood, plasma, or serum can be used to measure glucose. Most laboratories report plasma glucose values. Whole blood glucose values are 10% to 15% lower than plasma glucose levels because of plasma's higher water content. Thus, 60 mg/dL (3.3 mmol/L) would be the lower limit of normal for a whole blood glucose sample. Hence, it is essential to establish whether the glucose sample is blood or plasma. Additionally, this principle will pertain to glucose meters that can give blood or plasma glucose values. Another important consideration is that mixed venous blood samples can be dramatically lower than arterial glucose values. This will vary depending upon the insulin sensitivity of the individual and the prevailing insulinemia. In addition, fasting glucose samples of capillary and venous samples are similar, but glucose concentrations during an oral glucose tolerance test (OGTT) in capillary blood are significantly higher than those in venous blood. Therefore, hypoglycemic values obtained from mixed venous blood should be interpreted with care during an OGTT.[2]

Artifactual hypoglycemia can also occur if a blood glucose sample is not collected in a tube containing citrate buffer, for example, which will inhibit glycolysis. Without appropriate sample collection, glucose values can decrease by 10 to 20 mg/dL (0.5–1.0 mmol/L) per hour at room temperature. In addition, even if glucose samples are collected in tubes containing glycolytic inhibitors, artifactually low readings can be obtained if the sample remains unmeasured for many hours, if the sample contains large quantities of white blood cells, if the sample is heavily lipemic with triglycerides, or if the patient has polycythemia vera, Waldentrom macroglobulinemia, or a condition in which there is decreased capillary flow.[3]

KEY POINTS

- Level 1 hypoglycemia is defined as a plasma glucose below 70 mg/dL (3.9 mmol/L) but 54 mg/dL (3.0 mmol/L) or above. Level 2 hypoglycemia is a plasma glucose below 54 mg/dL (3.0 mmol/L), and level 3 hypoglycemia is a severe hypoglycemic event associated with significant neurologic deficits requiring assistance from a second party.

PHYSIOLOGY OF HYPOGLYCEMIA

Brain Fuel Metabolism

During typical physiologic conditions, the brain requires a constant and adequate supply of glucose. Under normal postabsorptive conditions (e.g., an overnight fast), the brain accounts for approximately 65% of whole-body glucose uptake. Following feeding, the amount of glucose taken up by the brain can increase, but insulin does not influence the kinetics of glucose in the brain as it does in other organs, such as liver or muscle. Although the brain was classically considered an insulin-insensitive organ, recent work has challenged this concept.[4] Several studies have elegantly demonstrated that insulin can regulate feeding mechanisms and energy expenditure in rodent models.[4] Additionally, insulin administration into areas of the hypothalamus has been demonstrated to regulate hepatic glucose output by decreasing glucose uptake and glycogen synthesis. Furthermore, studies in dogs[5] and mice[6] have demonstrated direct central nervous system effects of insulin to amplify autonomic nervous system (ANS) counterregulatory responses to hypoglycemia. Thus, accumulating data indicate that insulin can modulate several components of energy homeostasis via direct neuronal signaling in certain areas of the brain.

Although typically dependent upon glucose as a fuel, the brain can adapt and use other substrates. Thus, during periods of fasting, ketone bodies, lactate, and alanine can be used as alternative brain fuels.[7] Several studies have demonstrated experimentally that high levels of alternative substrates (β-hydroxybutyrate and lactate) can be infused during acute hypoglycemia with a concomitant reduction in neuroendocrine and ANS responses. This indicates that the brain has the capacity to switch from glucose to alternative substrates in a matter of hours. However, it should be noted that the concentrations of substrates infused experimentally are far higher than levels observed during most physiologic conditions (the exception is levels of ketone bodies that occur during prolonged fasting).

TABLE 38.1 **Causes of Hypoglycemia in Adults**

Type 1 and type 2 diabetes
Hypoglycemia in medicated or ill individuals
Drug-induced Hypoglycemia (see Table 38.3)
Critical illness (hepatic, renal and heart disease, malnutrition)
Hormonal deficiency
Non–islet cell tumors
Hypoglycemia in apparently well individuals
Hyperinsulinism (insulinoma, nesidioblastosis, post–gastric bypass)
Autoimmune hypoglycemia (insulin autoimmune and antiinsulin receptor antibody syndromes)
Other (factitious, reactive hypoglycemia, pregnancy)

During hypoglycemia, brain glucose uptake falls. The exact glycemic value for the start of decreased blood-to-brain glucose transport is debated but is thought to be around 65 to 70 mg/dL (3.6–3.9 mmol/L) in humans. As hypoglycemia deepens (approximately 54 mg/dL [3 mmol/L]), blood-to-brain glucose transport becomes rate-limiting for brain glucose metabolism. Glycolytic-derived lactate and a small amount of stored astrocytic glycogen can provide a short duration of fuel supply. The presence of detectable brain glycogen levels, even after hypoglycemia, support that brain glycogen is an important reservoir of glucose equivalents.[8] Brain glycogen depletion likely occurs after about 120 minutes of hypoglycemia, thus emphasizing the need for a continuous and adequate supply of glucose to the brain from the circulation. Recent studies have demonstrated that that the sympathoadrenal response to hypoglycemia is not in response to a decrease in whole-brain glucose metabolism.[9]

COUNTERREGULATORY RESPONSES DURING HYPOGLYCEMIA

As plasma glucose falls, a well-orchestrated response of multiple physiologic mechanisms is activated (Fig. 38.1). The initial defense is a reduction in endogenous insulin secretion. This occurs as plasma glucose levels fall to less than 80 mg/dL (4.4 mmol/L). The reduction in endogenous insulin in response to falling plasma glucose is often overlooked in the hierarchy of defenses against hypoglycemia. Extended follow-up data from the Diabetes Control and Complications Trial (DCCT) demonstrated that a stimulated C-peptide (i.e., endogenous insulin) was associated with a decreased risk of hypoglycemia.[10] Similarly, experience from islet cell transplantations clearly demonstrates that the ability to modulate endogenous insulin levels is also protective against episodes of hypoglycemia.[11] As glucose levels continue to fall at or around

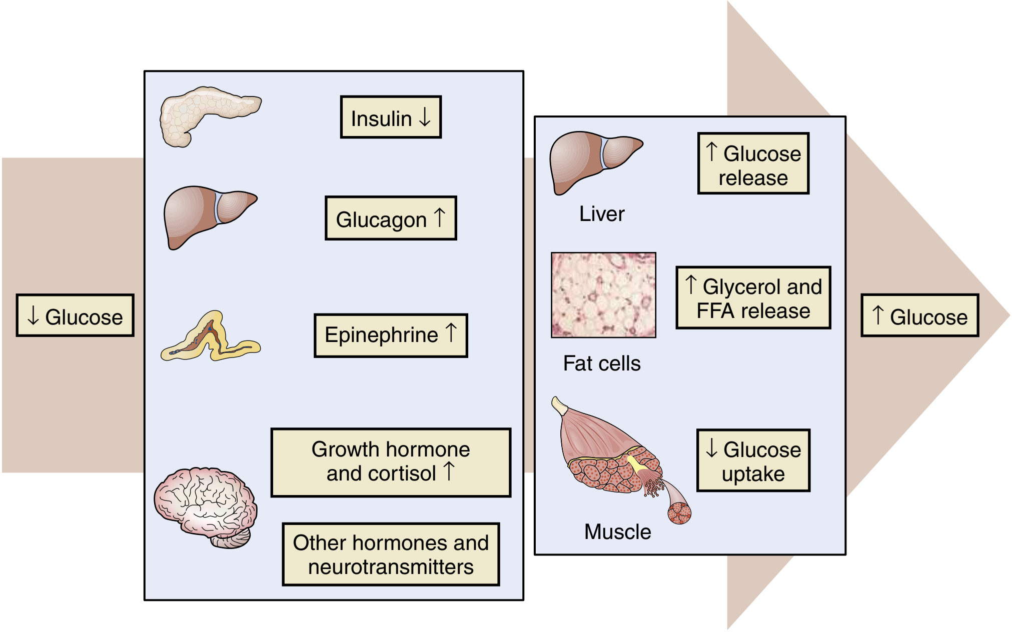

Fig. 38.1 Normal or healthy counterregulatory responses to hypoglycemia. As plasma glucose declines, powerful hormone regulation at the level of the pancreas, liver, and adrenal glands is activated. The liver, adipose tissue, and peripheral tissue respond to ultimately defend against a falling blood glucose. *FFA,* Free fatty acids. (From McDonnell ME, Umpierrez GE: Insulin therapy for the management of hyperglycemia in hospitalized patients. *Endocrinol Metab Clin North Am.* 2012; 41:175–201.)

70 mg/dL (3.9 mmol/L), a coordinated release of antiinsulin (counterregulatory hormones) occurs. Epinephrine (from the adrenal medulla), glucagon (pancreatic α cells), norepinephrine (sympathetic nerve endings and adrenal medulla), growth hormone (anterior pituitary gland), and cortisol (adrenal cortex) all have been demonstrated to have protective metabolic effects during acute or prolonged hypoglycemia. It should be noted that the release of neuroendocrine counterregulatory hormones and the inhibition of endogenous insulin secretion occur before a healthy adult can feel any symptoms of hypoglycemia. If plasma glucose continues to fall, at approximately 60 mg/dL (3.3 mmol/L), a series of autonomic (sometimes called neurogenic) signs and symptoms is activated. Autonomic warning responses to hypoglycemia include adrenergic and cholinergic symptoms. Adrenergic symptoms include palpitations, tremor, dry mouth, warmth, and anxiety. Cholinergic symptoms include sweating, hunger, and paresthesias. Signs of adrenergic activation include sweating and pallor. If the glucose level continues to fall, neuroglycopenic symptoms are activated at approximately 54 mg/dL (3.0 mmol/L). These include blurred vision, drowsiness, slurred speech, confusion, and difficulty concentrating. Defects in cognitive function are also apparent at this level of glycemia. If plasma glucose continues to fall, individuals can become drowsy, enter into a coma, and suffer seizures. Alternatively, individuals can become aggressive, which can be difficult to control and can be distinct from their usual personality. If severe hypoglycemia is prolonged, life-threatening events such as arrhythmias, myocardial infarction, and stroke, can occur.[12] Long-term cognitive damage and even death can occur if very severe hypoglycemia continues.[13] Although these represent typical responses to falling glucose levels, it should be appreciated that many patients have idiosyncratic neurologic and symptomatic responses to hypoglycemia that fall outside the classical description. Thus, it is worthwhile to measure the glucose level in anyone who presents with neurologic deficits and/or strange and uncharacteristic behavior.

The typical physiologic responses to hypoglycemia can be modified by a number of factors, including antecedent hypoglycemia, long-duration diabetes, age, gender, pregnancy, autonomic neuropathy, and use of certain drugs. These altered physiologic and pathophysiologic responses are discussed in detail in the following sections.

Insulin. Insulin is the principal physiologic factor that lowers plasma glucose. Insulin is secreted primarily in response to glucose, but amino acids, nonesterified fatty acids (NEFAs), β_2-adrenergic stimulation, and acetylcholine can also activate secretion of the hormone. Insulin secretion can be inhibited by hypoglycemia, insulin itself, somatostatin, and α_2-adrenergic activity.[14]

Insulin is released into the portal vein following secretion from pancreatic β cells. As the result of hepatic extraction, portal vein levels of insulin are approximately 2-fold higher than peripheral levels. Insulin lowers plasma glucose through several different mechanisms. Endogenous glucose production is inhibited directly first by suppressing hepatic glycogenolysis and then by restraining hepatic and renal gluconeogenesis. Simultaneously, insulin increases glucose uptake into insulin-sensitive tissues (primarily muscle but also liver and adipose tissue). As soon as the rate of exit of glucose exceeds the rate of entry of the substrate into the circulation, then the plasma glucose level starts to fall. Additionally, insulin can suppress glucose production indirectly by restraining lipolysis. (This restricts the flow of glycerol, an important gluconeogenic precursor, and NEFAs, which provide energy for gluconeogenesis.) Insulin also restricts proteolysis, which suppresses the flow of amino acids as gluconeogenic precursors.

Insulin secretion wanes as blood glucose returns to postabsorptive levels, removing inhibition of hepatic glucose production that will sustain fasting glucose levels until the next meal. After a typical overnight fast, the liver produces at least 85% of the glucose that enters the circulation. At this point, about 50% to 66% of glucose production is driven by glycogenolysis, and the rest is gluconeogenesis. If the fast were to continue, then most glucose production would be driven by gluconeogenesis, and glycogen stores would be depleted. After 48 hours of fasting, gluconeogenesis is responsible for 80% of glucose output. By 72 hours, gluconeogenesis becomes the only source of glucose production in the body.

Glucagon. Glucagon is released from the α cells in the islet of Langerhans. Similar to insulin, a number of physiologic factors can regulate secretion. These include hypoglycemia, amino acids, catecholamines (epinephrine and norepinephrine via β_2-adrenergic mechanisms), and free fatty acids.[15] Inhibitors of glucagon release include insulin and somatostatin. The regulation of glucagon release during hypoglycemia in humans is still undecided.[16] Normal glucagon secretion is observed in the setting of islet cell denervation and in *in vitro* pancreas preparations, suggesting that loss of these extrapancreatic influences does not explain the loss of glucagon response observed in severe β cell failure (type 1 diabetes mellitus [T1DM] or long-duration diabetes). Direct α cell stimulation of glucagon is signaled by a decrease in insulin secretion from the β cell in the setting of a low plasma glucose. Additionally, convincing data demonstrate that autonomic input (both sympathetic and parasympathetic) into the pancreas can also result in glucagon secretion.

Glucagon's physiologic actions are restricted almost exclusively to the liver, stimulating a rapid increase in hepatic glucose production over a period of 10 to 15 minutes. The initial rise in glucose output is provided by an increase in hepatic glycogenolysis. If hypoglycemia continues, glucagon can stimulate hepatic gluconeogenesis, but only if three carbon precursors such as glycerol, lactate, and amino acids are present.

Epinephrine and Norepinephrine. Epinephrine (adrenaline) is released from the adrenal medulla. Similar to glucagon, the hormone can act rapidly to increase hepatic glucose output by stimulating hepatic glycogenolysis. If hypoglycemia continues, and three-carbon precursors are present, epinephrine will stimulate gluconeogenesis in the liver and kidneys.[17] Unlike glucagon, epinephrine has important effects on peripheral tissues. Epinephrine can restrict insulin-stimulated glucose uptake in skeletal muscle, which, when quantified in terms of maintaining glucose in the circulation, is greater than the contribution made by any increase in endogenous glucose production. This latter property of epinephrine is especially important in the defense against hypoglycemia that typically is encountered in clinical practice. Unlike the model of rapid hypoglycemia produced during an insulin tolerance test, the usual clinical course involves a slower decline into hypoglycemia and a more protracted duration of low glycemia, which, during the night, can last up to several hours. With the acute induction of hypoglycemia caused by a large bolus of rapid-acting insulin, it is the activation of endogenous glucose production that is the primary physiologic defense against hypoglycemia, but in a model of more prolonged hypoglycemia, the restriction to insulin-mediated glucose uptake is paramount.[18] Epinephrine's important metabolic effects, which are mediated via β_2-adrenoreceptors, also include stimulation of lipolysis to provide substrate (glycerol) and energy (NEFA) for gluconeogenesis. Additional effects on muscle provide lactate, pyruvate, and amino acids for gluconeogenic precursors.

Norepinephrine has similar metabolic actions to those of epinephrine. However, because 90% of norepinephrine is taken up at the level of sympathetic clefts, and a further 90% of the remaining catecholamine is taken up by the gut and then the liver, the increase in circulating norepinephrine during hypoglycemia is relatively modest (~50% as compared with the 30-fold elevations that can occur with epinephrine).

Cortisol and Growth Hormone. The acute metabolic effects of cortisol and growth hormone are similar.[19,20] Both can increase glucose production through increases in gluconeogenesis. Both hormones also can inhibit insulin-stimulated peripheral glucose uptake and can increase lipolysis and proteolysis. However, prolonged hypoglycemia (3–5 hours) is needed before the metabolic effects of growth hormone or cortisol are measurable, and even at that time represents only approximately 20% to 25% of the action of epinephrine. Thus, although chronic deficiencies of cortisol and/or growth hormone can cause hypoglycemia, these hormones serve no demonstrable function in the defense against acute hypoglycemia.

Hypoglycemia-Associated Neuroendocrine and Autonomic Failure

As discussed earlier, the four primary physiologic defenses against falling plasma glucose include inhibition of endogenous insulin secretion, release of glucagon and epinephrine, and symptomatic cues to ingest carbohydrate (Fig. 38.1). Unfortunately, in patients with diabetes, all of these physiologic defenses can become defective and/or deficient. In T1DM and in long-duration type 2 diabetes mellitus (T2DM), the individual becomes critically insulin deficient, and thus the first physiologic line of defense (modulation of endogenous insulin) becomes lost (Fig. 38.2). After varying periods of duration of disease (~5 years), the ability of individuals with T1DM to release glucagon in response to hypoglycemia is lost (Fig. 38.2).[21,22] This defect also occurs to a similar extent in long-duration T2DM but is more gradual.[23] Thus, individuals are left with an attenuated epinephrine response. Sympathoadrenal activation is shifted to a lower glycemic threshold by recent antecedent hypoglycemia, prior exercise, and sleep. The lone attenuated epinephrine response causes a defective counterregulatory response, increasing the risk of severe hypoglycemia by 25 times, and hypoglycemic unawareness, the diminished or loss of the warning symptoms of hypoglycemia, the absence of which delays ingestion of carbohydrates. Hypoglycemic unawareness also confers an increased risk of hypoglycemia. Thus, the term hypoglycemia-associated autonomic failure (HAAF) describes the condition of insulin and glucagon deficiency in which antecedent hypoglycemia (or exercise or sleep) causes an attenuated epinephrine response and hypoglycemic unawareness that results in a vicious cycle of hypoglycemia[24] (Fig. 38.3).

Fig. 38.2 Counterregulatory response to hypoglycemia in type 1 diabetes mellitus and long-duration type 2 diabetes mellitus. As plasma glucose declines, impaired insulin and glucagon counterregulatory responses leave on the epinephrine response to defend against a falling glucose. In some cases, the epinephrine response is also impaired. This can result in an increased frequency of moderate and severe hypoglycemia. *FFA,* Free fatty acids.

Pathophysiology. Although the concept of HAAF is supported by an improvement in the epinephrine response to hypoglycemia with 2 to 3 weeks of strict avoidance of hypoglycemia, the mechanisms responsible for the syndrome of HAAF are not fully elucidated.[22,25] β cell failure in T1DM and long-duration T2DM explains the inability of insulin levels to decline with falling glucose levels. The glucagon defect appears to reside at the level of the islet. In diabetes with defective β cell function, α cells have a persistent inhibitory signal resulting in a diminished, if not absent, glucagon response. This is supported by evidence that glucagon response is maintained in scenarios in which denervation to the islet has been investigated (i.e., pancreas transplant, spinal cord transections) and in the setting of amino acid administration, a known glucagon-releasing stimulant. Lastly, the loss of insulin and glucagon secretion are correlated.

HAAF appears to only result when the sympathoadrenal response to hypoglycemia are affected. This is felt to reside in the central nervous system or the pathways by which signals are carried to and from the brain. The current hypotheses include the systemic-mediator hypothesis, the brain-fuel transport hypothesis, the brain metabolism hypothesis, and the cerebral-network hypothesis, which are described in detail by Cryer.[22]

Risk Factors. The risk factors that increase HAAF include: the extent (and duration) of β cell insulin deficiency, history of severe hypoglycemia, history of hypoglycemic unawareness, recent hypoglycemia before exercise or sleep, and intensive glucose control.[26] Additionally, it also appears that, in healthy persons, estrogen is a major mechanism responsible for sexual dimorphic counterregulatory responses during hypoglycemia.[27] Women appear to be more resistant than men to the blunting effects of prior hypoglycemia. Thus, antecedent hypoglycemia can have up to a 2-fold greater suppressive effect on subsequent counterregulatory responses in men than in women.[28]

Strategies to Improve Counterregulatory Responses During Hypoglycemia. Strategies for improving ANS and neuroendocrine responses during hypoglycemia are ongoing and are often carried out in parallel with investigation into the mechanism of HAAF. As mentioned previously, 2 to 3 weeks of strict avoidance of hypoglycemia with treatment changes or deescalation of glycemic goals results in improvement in the epinephrine response to hypoglycemia. Further strategies to reduce and monitor for hypoglycemia (i.e., continuous glucose monitoring) are discussed in "Strategies to Reduce Hypoglycemia."

Preclinical research approaches to increase neuroendocrine responses during hypoglycemia are many, and a few are presented here. The ventral medial nucleus (VMH) is a key region of the brain for detecting hypoglycemia. Activation of adenosine monophosphate–activated protein kinase (AMPK) appears to play a role in VMH sensing of hypoglycemia, and increases in AMPK action (a possible therapeutic target) can increase glucagon and epinephrine responses during hypoglycemia.[29] Activation of the VMH adrenergic receptors acutely appears to enhance the counterregulatory response to hypoglycemia; however, frequent activation may contribute to counterregulatory failure. Peroxisome-proliferator–activated receptor-γ agonists are known to activate AMPK and fructose, which under certain conditions can inhibit glucokinase, and increase counterregulatory responses in both healthy men and those with T1DM.[30] Treatment with low-dose carvedilol was found to improve VMH lactate levels, epinephrine, and feeding response in nondiabetic rodents with recurrent hypoglycemia.[31] Terbutaline, an epinephrine-stimulating β_2-adrenergic agonist, or alanine, a glucagon-releasing amino acid, before bed increases plasma glucose levels during the night and prevents nocturnal hypoglycemia.[32] Opioid receptor blockade, via treatment with naloxone, during hypoglycemia and antecedent exercise was shown to prevent blunting of responses (epinephrine and endogenous glucose production) to next-day hypoglycemia in individuals with T1DM.[33,34] Prolonged (i.e., weeks) use of two different selective serotonin reuptake inhibitors (sertraline and fluoxetine) has led to dramatic (30% to 60%) increases in ANS (epinephrine) responses during hypoglycemia, highlighting the possible role of serotonin in modulating counterregulatory responses during hypoglycemia.[35]

KEY POINTS

- Regulation of endogenous insulin, glucagon, and epinephrine is the primary acute hormonal response against an acutely falling blood glucose. Norepinephrine, cortisol, and growth hormone play little or no role in the acute defense against hypoglycemia.
- The term "hypoglycemia-associated autonomic failure" describes the condition in which antecedent hypoglycemia (or exercise or sleep) causes an attenuated epinephrine response and hypoglycemic unawareness that results in a vicious cycle of hypoglycemia.

GENERAL APPROACH TO THE PATIENT

Acute Treatment of Hypoglycemia

Treatment is aimed at restoring euglycemia (regardless of the cause), preventing recurrences, and, if possible, alleviating the underlying etiology.[36] Most cases of hypoglycemia in patients with diabetes are self-diagnosed and treated without medical emergency services. Initial treatment generally involves consumption of 15 to 20 g of simple carbohydrate. In severe hypoglycemia, with a measured glucose of less than 54 mg/dL (3.0 mmol/L), 20 to 30 g of carbohydrate may be necessary. Blood glucose should be remeasured within 15 minutes of oral carbohydrate, and the process should be repeated if the individual remains symptomatic, or in the setting of persistent hypoglycemia. These measures may be less effective if acarbose is prescribed because of the inhibition of carbohydrate absorption from the gut. In these cases, pure glucose gel or tablets are recommended. Additionally, physiologic or medication-induced delayed gastric emptying may result in unreliable absorption of glucose. Fat-containing foods will impair the absorption of glucose and should be avoided.

With more severe hypoglycemia preventing oral administration of carbohydrate, glucagon given subcutaneously, intramuscularly, or intranasally should be sufficient to raise the blood glucose concentration and revive the patient so that oral carbohydrate can be given. Intranasal glucagon has been shown to be as effective as intramuscular and subcutaneous glucagon in the treatment of hypoglycemia.[37] This newer glucagon preparation, which is needle free, is significantly easier to use than the current glucagon emergency kits, particularly in the pediatric population or in those with limited dexterity.

Comatose patients should receive intravenous glucose, followed by an infusion to maintain glucose at around 80 to 100 mg/dL (4.4–5.6 mmol/L). Protocols include a 25-g bolus of 50% dextrose in water (D50), but some use 10% dextrose or a combination of dextrose concentrations with a continuous infusion of 25 g of D50 or 1 g/kg of body weight in D50 in a large-gauge port and vein. A 10% or 20% dextrose infusion can be provided in a peripheral vein. A sulfonylurea or meglitinide overdose or exogenous long-acting insulin can result in prolonged hypoglycemia as long as several days requiring sustained intravenous glucose infusion aimed at keeping the blood glucose level at approximately 80 to 100 mg/dL (4.4–5.6 mmol/L) to avoid hyperglycemia, causing further stimulation of insulin secretion and setting in motion a vicious cycle. When other drugs are involved, their use should be discontinued if possible. Occasionally, diazoxide or a somatostatin analog may be needed to inhibit insulin secretion.

Blood glucose levels should be monitored initially every 15 to 30 minutes and subsequently at 1- to 2-hour intervals. Once euglycemia is achieved, a complex meal should be provided to restore any lost glycogen stores. In other conditions, the underlying disorder (e.g., sepsis, heart failure, endocrine deficiency) should be treated, and the blood glucose level should be supported.

Evaluation of the Hypoglycemic Patient

In an individual with diabetes, a careful review of the duration of diabetes, treatment plan, adherence, and timing of hypoglycemia to mealtimes, medication administration, and exercise are critical (Table 38.2). Strategies to reduce hypoglycemia in diabetes are discussed later. Without a diagnosis of diabetes, the first step in the evaluation of hypoglycemia is to establish Whipple's triad (low plasma glucose, typical hypoglycemic symptoms, and resolution of symptoms with euglycemia). It is important to determine what the patient's symptoms were. When did they occur in relation to the patient's last meal, and what was the patient doing when the episode occurred? Was it an isolated event, or had it occurred before? How frequently do these episodes occur? Is there any pattern to the occurrences? How long have these events been occurring? Did weight gain or weight loss occur during this period? Is the patient taking any medications? If so, he or she should be checked to make sure that no mistake has been made. Did the patient lose consciousness? If so, were premonitory signs present? Was hypoglycemia documented? Did the patient recover spontaneously? What did the patient do to prevent recurrences or relieve symptoms? What is the patient's occupation? Does the patient or any immediate relative have diabetes? If so, how is it being treated? Does the patient have any medical conditions? Do family members have any endocrine disorders? For example, a family history of autoimmune disorders should raise the suspicion of Addison disease.

In a retrospective study, diabetes, infection/sepsis, renal and liver disease, and malignancies accounted for the majority of emergency room cases of hypoglycemia.[38] Virtually all patients had decreased level of consciousness, giddiness, or other nonspecific symptoms. The incidence of death was approximately 16 per 1000 emergency department visits. Among diabetic patients, 60% had intensive control of blood sugars with oral hypoglycemic agents, insulin, or both.

Most outpatients who have a disorder that is causing hypoglycemia should describe discrete episodes. Classically, premonitory symptoms such as a feeling of anxiety, hunger, blurred vision, difficulty thinking, weakness and sweating, and palpitations will be noted. Loss of consciousness can occur. With repetitive episodes, patients learn that they can abort these symptoms by eating; therefore, patients often have a history of weight gain. Spells similar to those caused by hypoglycemia can represent a vasovagal reflex, cardiac arrhythmia, a convulsive disorder, orthostatic hypotension, or a transient ischemic attack. In mild cases of insulinoma, spells might occur only after vigorous exercise or prolonged fasting. On the other hand, skipping lunch and having several cocktails before dinner can precipitate an isolated hypoglycemic episode in an otherwise healthy person. The history (e.g., prior pituitary surgery, symptoms of galactorrhea, amenorrhea, impotence, or endocrine insufficiency, as with thyroid replacement therapy) can provide clues to the possibility of hypopituitarism. The patient's occupation or family diseases can be important with regard to access to hypoglycemia-producing drugs (e.g., insulin, sulfonylureas) or multiple endocrine neoplasia type 1 (MEN1).

The physical examination can be useful in excluding carotid disease, orthostatic hypotension, severe cardiac and hepatic disease, hypothyroidism, cachexia, and cancer, which should be obvious at the stage at which they would cause hypoglycemia. Routine laboratory testing can exclude renal insufficiency or can raise the possibility of adrenal insufficiency (hyponatremia). If all of the discussed are negative, and prior hypoglycemia has not been documented unequivocally, this must be done before one proceeds with other diagnostic tests.

KEY POINTS

- The general approach should be to identify hypoglycemic quickly. Treat hypoglycemia with oral simple carbohydrate (15–30 g). If severe or comatose, the patient should be treated with glucagon and may require intravenous glucose. Assessment of the underlying etiology may require additional/alternate treatment. Individuals should be monitored for initial improvement at short intervals (15–30 min). The last steps are to address the underlying condition.

HYPOGLYCEMIA IN DIABETES

Hypoglycemia is associated with significant morbidity and can be fatal.[39] Hypoglycemia and the fear of hypoglycemia are significant barriers to achieving adequate glucose control. Almost immediately after the discovery of insulin in the early 1920s, hypoglycemia was recognized as an unpleasant and dangerous side effect of therapy. More than 90% of all patients with T1DM have suffered an episode of hypoglycemia. Typically, a patient with T1DM will experience two to 10 episodes of subjective hypoglycemia per week.[40] Nocturnal hypoglycemia is frequent and prolonged with conventional therapy. Episodes of major hypoglycemia requiring assistance or hypoglycemic events resulting in seizures or coma increase with intensive management.[41] Glycosylated hemoglobin (HbA1c) is inversely associated with risk for

TABLE 38.2 Diagnostic Approach to an Adult With Documented Fasting Hypoglycemia

1. Consider the most likely disorders (drugs, critical illness, endocrine deficiency, non–β cell tumor, and insulinoma) while supporting the plasma glucose concentration if necessary.
2. Examine the history, physical examination, and available laboratory data for clinical clues to include or exclude the above categories.

Cause	Response
Insulin- or sulfonylurea-treated diabetes	Adjust the therapeutic regimen
Use of other drugs known or suspected to cause hypoglycemia	Discontinue use of the drug
Hepatic, renal, or cardiac failure; sepsis; or inanition	Treat the underlying disorder
Anorexia, weight loss, change in skin pigmentation, known pituitary or adrenocortical disease, hypotension, hyponatremia, hyperkalemia	Evaluate for adrenocortical/pituitary insufficiency
Known non–β cell tumor, mass on examination or imaging studies	Check for high IGF-2 or IGF-2:IGF-1 ratio

3. In the absence of clinical clues, consider medication error, endogenous hyperinsulinism (see Tables 38.1 and 38.3), and surreptitious or malicious insulin secretagogue or insulin administration.

IGF, Insulin-like growth factor.

episodes of severe hypoglycemia, but the extent of risk depends on the defined threshold.[41,42] The duration of T1DM also plays an important role in increasing the frequency of severe hypoglycemia. Recent data from a 30-year follow-up of the DCCT/Epidemiology of Diabetes Interventions and Complications trial[42] demonstrate that the frequency of severe hypoglycemia remains at a rate of 36 to 41 episodes per 100 patient-years, even among those with longer duration diabetes and similar HbA1c levels. Lower HbA1c and younger age at study entry were risks for severe hypoglycemia.

Because of the 10-fold greater incidence of T2DM, the total episodes of hypoglycemia are greater than what occurs in T1DM. However, the risk and frequency of hypoglycemia are considered to be much lower in T2DM as compared with T1DM. This is undoubtedly true in patients with T2DM treated with a noninsulin secretagogue or combination therapy of metformin, thiazolidinedione, dipeptidyl peptidase-4 inhibitor, sodium-glucose cotransporter-2 inhibitor, α-glucosidase inhibitor, and/or a glucagon-like peptide-1 (GLP1) agonist. However, the incidence of hypoglycemia increases sharply in longer duration (insulin-requiring) T2DM. Recent clinical trials investigating insulin replacement strategies in T2DM report hypoglycemia five times more often compared with metformin.[43] Hypoglycemia requiring any assistance was more common with intensive glucose control compared with standard care; however, as intensive control was relaxed, rates of hypoglycemia equalized.[44] Rates of severe hypoglycemia have improved for patients over 75 years of age with T2DM.[45] Unlike observations in T1DM, individuals with T2DM appear to be at an increased risk for severe hypoglycemia at both near-normal (<6%) and poorly controlled (≥9%) HbA1c values.[46]

Mortality and Cardiovascular Disease

Death from hypoglycemia can be considered rare, given the very large number of episodes of hypoglycemia that occur in clinical practice. Mortality owing to hypoglycemia is estimated to be less than 8% in individuals with T1DM under 56 years of age and 4% in all people with diabetes under 50 years of age.[12]

Initially, it was thought that the rate of cardiovascular disease in T2DM may be reduced with more intensive glycemic treatment compared with standard control; however, subsequent large trials failed to show this benefit.[12] Additionally, intensive control was associated with an increased risk for severe hypoglycemia compared with standard control and an increase in mortality. Risks for hypoglycemia included long-duration diabetes, advanced age or frailty, a history of hypoglycemia, and known established atherosclerotic or microvascular disease. However, low HbA1c levels do not appear to be correlated with increased cardiovascular events if treated with medications that do not cause hypoglycemia. In T1DM and T2DM studies, individuals with hypoglycemia have a 1.5- to 6-fold increased risk of cardiovascular outcomes and mortality compared with those with no hypoglycemia. This increased risk can extend up to 1 year after the hypoglycemic event. Severe hypoglycemia appears to be an indicator of increased risk of cardiovascular events, cardiovascular mortality, and all-cause mortality, regardless of treatment goals, particularly if the individuals had an elevated risk of cardiovascular disease at baseline.[39] Experts continue to debate whether these results are causative or confounding. Hypoglycemia has been associated with electrocardiogram changes, arrhythmias, and hypercoagulable and prothrombotic states.

Strategies to Reduce Hypoglycemia

Glycemic Targets. Glycemic targets and therapies in diabetic patients should be individualized.[47] Although a HbA1c goal for many nonpregnant adults of less than 7% is reasonable, a lower HbA1c goal of less than 6.5% may be appropriate, if this can be achieved without significant hypoglycemia. However, a relaxed glycemic goal of less than 8% are appropriate in those with a history of severe hypoglycemia, multiple comorbid diseases, including advanced diabetic complications, or in those with long-duration diabetes who are unable to achieve glycemic control despite maximized treatment, education, and resources.

In hospitalized patients, hypoglycemia is associated with short- and long-term mortality.[48] Use of electronic treatment order sets and hypoglycemia protocols increases the likelihood of time in target range without increasing hypoglycemia and reduces severe hypoglycemic events.[49] Additionally, remote management of inpatients with diabetes by specialists was found to reduce hypoglycemia.[50] For most hospitalized patients, a glucose target of 140 to 180 mg/dL (7.8–10.0 mmol/L) is recommended.[51] However, selected patients may benefit from more intensive glucoses targets (110–140 mg/dL [6.1-7.8 mmol/L]) if hypoglycemia can be avoided. These recommendations were based on the Normoglycemia in Intensive Care evaluation and Survival Using Glucose Algorithm Regulation study, which demonstrated that moderate inpatient glucose targets showed no treatment advantage and slightly improved mortality compared with intensive control.[52] Additionally, hypoglycemia was 10 to 15 times higher in the intensively treated group.

Treatment Regimens and Technology. By far the most common cause of hypoglycemia in diabetes is medication (Table 38.3). Hypoglycemia induced by oral insulin secretagogues is much less frequent than that caused by insulin but in certain instances can still be common. For example, hypoglycemia can occur in up to approximately 35% of patients receiving glyburide or repaglinide, which are glucose-independent. Hypoglycemia rates are lower in agents with glucose-dependent insulin secretion (i.e., stimulation of insulin release is reduced during periods of hypoglycemia). Thus, the percentage of patients who experience hypoglycemia when receiving glimepiride, glipizide XL, gliclazide, or nateglinide is lower, in the range of 5% to 10%. However, combination of even glucose-dependent insulin secretagogues with agents such as insulin or GLP1 agonists can result in a much higher frequency of hypoglycemia (>35%). Generally, newer sulfonylureas produce less hypoglycemia than do older first-generation sulfonylureas such as chlorpropamide. Severe hypoglycemia remains relatively uncommon with sulfonylureas, at 0.8%.[53]

Over the last generation, interest has increased in replacing insulin in the most physiologic manner for patients with diabetes. In the 1980s, the introduction of recombinant human insulin reduced the formation of antibodies and provided more predictable pharmacokinetic profiles. The next decade produced analog insulins that initially were designed to provide a quicker onset and a shorter duration of action. These insulins (lispro, aspart, glulisine) were designed to reproduce more closely the typical physiologic prandial spikes of insulin observed following meals. The second wave produced long-acting basal types of insulin (glargine, detemir, degludec) designed to mimic background constitutive insulin release. Studies in T1DM have demonstrated that hypoglycemia (particularly nocturnal) can be reduced when short-acting analogs rather than regular (soluble) insulin are used.[54] Similarly, long-acting analogs have been demonstrated to reduce daytime and severe hypoglycemia by 26% and 36%, respectively, in patients with T2DM when compared with neutral protamine Hagedorn–based regimens.[55] Thus, current recommendations are to use analog-based insulin replacement regimens whenever possible. Inappropriate dosing or timing of insulin administration to food intake is a common cause of hypoglycemia in an individual with diabetes.

Continuous Subcutaneous Insulin Infusion. Continuous subcutaneous insulin infusion (CSII), or insulin pump, development began in the 1970s and over the past 20 years has become a major method of insulin replacement in the United States. Although

widely acknowledged for its usefulness, the cost of treatment (pump and supplies) has restricted a more widespread acceptance of this technology. However, CSII in individuals with T1DM does not appear to consistently or significantly reduce the risk of severe hypoglycemia compared with traditional insulin injection therapy.[56,57]

Continuous Glucose Monitors. Continuous glucose monitoring (CGM) and flash real-time glucose monitoring is now an established technology in clinical practice. A variety of devices can be worn in combination with an insulin pump or independently. In studies of CGM in individuals with T1DM using reduction of hypoglycemia as an endpoint, time below target (defined as <70 and <54 mg/dL [3.9 and 3.0 mmol/L]) is reduced.[47] CGM is superior to self-monitoring of blood glucose in terms of time spent in target and reduction of severe hypoglycemia.[58] The results are less robust in CGM use in T2DM.[59] CGM compared with flash glucose monitoring was more successful in reducing level 2 hypoglycemia in individuals with T1DM and a history of hypoglycemic unawareness.[60] Continuous glucose monitors are not approved for inpatient use. However, studies have demonstrated a reduction in hypoglycemia in various inpatient populations, particularly those in intensive care units (ICUs).[61] CGMs may be particularly useful, given that ICU patients may be unable to report hypoglycemia symptoms, for example during altered mental status or intubation, and may have blunted counterregulatory responses to hypoglycemia.

Integration of Continuous Subcutaneous Insulin Infusion and Continuous Glucose Monitoring. Certain insulin pumps with sensor-augmented features suspend basal insulin when low blood glucose is detected. Furthermore, an additional predictive feature can suspend insulin delivery based on a sensor-predicted low blood glucose algorithm. Use of these features has been shown to reduce the time in hypoglycemia and daytime and nocturnal severe hypoglycemia compared with sensor augmented treatment.[62,63]

"Hybrid" closed-loop systems automatically modify basal insulin delivery using real-time sensor glucose trends but do not independently dispense bolus insulin. There is a dedicated hypoglycemia safety algorithm. Compared with sensor-augmented insulin pump treatment, the Medtronic MiniMed 670G demonstrated less time in hypoglycemia, and the Tandem Control-IQ showed no increase in time in hypoglycemia, when compared with sensor-augmented therapy.[64,65]

Pancreas and Islet Cell Transplantation. One of the major criteria for consideration of pancreas or islet cell transplantation (see Chapter 41) is complete insulin deficiency with a history of recurrent severe hypoglycemia. Pancreas and islet cell transplantation may improve hormonal response to insulin-induced hypoglycemia.[66] Initially, after pancreatic transplantation, both basal and glucose-stimulated insulin secretion are increased compared with normal controls. This occurs in the absence of meaningful innervation of the transplanted pancreas. In response to hypoglycemia, individuals with T1DM having received a whole pancreas transplant demonstrate a partial suppression of endogenous insulin that is sufficient to result in appropriate glucagon secretion. Whole pancreas transplant results in normalization of the glycemic thresholds for counterregulatory hormone response (epinephrine and growth hormone) to hypoglycemia; however, in whole pancreas transplantation, the epinephrine response is only partially restored.

In individuals with T1DM who receive islet allotransplantation, endogenous insulin secretion is suppressed with hypoglycemia, and glucagon secretion is partially restored. The transplanted islet cell mass is critical to the extent of recovery of the glucagon response. Additionally, normalization of the glycemic thresholds for counterregulatory hormone response to hypoglycemia are observed within 6 months; however, the extent of the epinephrine response may be partial and/or delayed for months to years. In individuals receiving islet autotransplantation, the extent of the glucagon response recovery may depend on the transplant location (hepatic or nonhepatic site). For reference, nonhepatic site islet cell autotransplantation results in a normal glucagon response to hypoglycemia.

Exercise. Individuals with T1DM or longstanding T2DM who exercise are at increased risk for hypoglycemia during and many hours after exercise as a result of imperfect insulin replacement, increased insulin action, reduced glucagon replacement, and impaired counterregulatory responses.[67] In general, if an individual is experiencing exercise-related hypoglycemia, it is appropriate to consider alterations to his or her insulin regimen (both basal and bolus) and carbohydrate intake. Short high-intensity sprints, resistance exercise before aerobic exercise, and activity timing are all strategies to reduce the risk of hypoglycemia. The risk of nocturnal or delayed hypoglycemia (out to 48 hours) can be reduced with temporary basal reductions, bedtime snacks, and use of continuous glucose monitoring.

It should be noted that hypoglycemia has been documented after prolonged strenuous exercise (i.e., marathon runners), sometimes in the setting of medications like β blockers. However, most instances of exercise-associated hypoglycemia are asymptomatic, self-limited, and readily reversed by carbohydrates.

General Considerations. All visits with individuals with diabetes should include an assessment of hypoglycemia and hypoglycemia symptoms.[47] Additionally, in individuals who are prescribed medications that are more likely to cause hypoglycemia, heightened awareness and consideration of hypoglycemic unawareness is important. Recurrent level 3 episodes of hypoglycemia or hypoglycemic unawareness should prompt renewed hypoglycemia education and reassessment of the treatment plan and goals. For individuals who are prescribed insulin, a pattern of hypoglycemia or one level 3 hypoglycemic episode should result in adjustment of the treatment plan and strict avoidance of hypoglycemia for at least 2 weeks. Ongoing evaluation of cognitive function is important, as level 3 hypoglycemia is associated with established or declining cognitive function. Vulnerable groups, including children and older adults, may be unable to convey their symptoms or needs effectively. For those with diabetes who use intermittent fasting or are of Islamic faith and observe the month-long Ramadan fast, patient education, continuous glucose monitoring, and diet modification, in conjunction with adjustment of insulin timing and dosing, should be considered to prevent hypoglycemia.[68] Specific situations, including driving and recreational exercise or sports, may require relaxed glucose control to avoid hypoglycemia. Frequency of testing should be increased, and a glucose source should be readily available.

KEY POINTS

- In type 1 and type 2 diabetes mellitus studies, individuals with hypoglycemia have a 1.5- to 6-fold increased risk of severe adverse cardiovascular outcomes and mortality compared with those with no hypoglycemia.
- Glycemic targets and therapies in diabetic patients should be individualized. Although a HbA1c goal of less than 7% is reasonable for many nonpregnant adults, a lower HbA1c goals of under 6.5% may be appropriate in the absence of hypoglycemia. A relaxed glycemic goal of below 8% is appropriate in some individuals.

HYPOGLYCEMIA IN THE ABSENCE OF DIABETES

In nondiabetic individuals, hypoglycemia is rare, with blood glucose levels of less than or equal to 70 mg/dL (≤3.9 mmol/L) and less than or equal to 54 mg/dL (≤3.0 mmol/L) reported in as few as 1082/100,000 and 910/100,000 emergency medical service encounters, respectively.[69] In hospitalized patients, nondiabetic hypoglycemia accounts for 20% to 30% of the hospitalizations with hypoglycemia. Mortality in hospitalized patients who experienced hypoglycemia was 15%. Older age, low body mass index, renal and heart failure, chronic liver disease, sepsis, and malignancies are risk factors for hypoglycemia.[70]

Establishment of Whipple's triad is integral to confirming a hypoglycemic disorder.[21] The threshold for symptomatic hypoglycemia shifts to lower plasma glucose levels in individuals with recurrent hypoglycemia. Fingerstick or CGM low glucose values should be confirmed with a low plasma glucose level. Well-documented severely low blood glucose (<40 mg/dL [2.2 mmol/L]) in the absence of symptoms should still be investigated. Typical hypoglycemic symptoms with normal plasma blood glucose (>70 mg/dL [3.9 mmol/L]) are not consistent with a hypoglycemic disorder. Underlying causes of hypoglycemia are diverse in people without diabetes, and diagnosis can be complex and requires careful consideration of patient history, and potentially further workup. Causes of hypoglycemia are generally divided into those in medicated or ill individuals and those in apparently well individuals.

HYPOGLYCEMIA IN MEDICATED OR ILL INDIVIDUALS

Drug-Induced Hypoglycemia. Some 23% of hospital admissions for adverse drug events are attributed to drug-induced hypoglycemia.[71] Insulin and insulin-secreting medications (i.e., sulfonylurea or meglitinides) are common causes of drug-induced hypoglycemia.[21] This is discussed in "Hypoglycemia in Diabetes." Alcohol is a common cause of hypoglycemia; however, hypoglycemia is an uncommon complication of alcohol abuse.[72] In a series of deaths caused by hypoglycemia, alcohol was the most common causative agent.[73] The most common situation is a glycogen-depleted state, including chronic liver disease or circumstances in which an individual drinks after a considerable fast or drinks and then fasts. In the latter situation, blood alcohol levels can be low, but cellular metabolic effects at the liver persist. Alcohol induces hypoglycemia by inhibiting gluconeogenesis, with evidence of impaired counterregulatory hormone responses. Thus, in a patient with suspected alcohol-induced hypoglycemia, oral or intravenous glucose is the treatment of choice. If there is a clinical concern for malnutrition, thiamine supplementation should be provided to avoid Wernicke's encephalopathy.

Many of the drugs listed in Table 38.3 have been reported to cause hypoglycemia, generally the subject of isolated case reports, and their etiologic significance remains to be established.[21,71] Often, dosing was correct, and risk factors for associated hypoglycemia were older age, renal, liver or systemic disease, or coadministration of insulin or sulfonylurea. However, their use in a patient with otherwise unexplained hypoglycemia should be discontinued whenever possible.

Critical Illness. In a retrospective study of critically ill patients, mortality was 56% among patients with severe hypoglycemia (<40 mg/dL [<2.2 mmol/L]) compared with 40% among controls.[74] Risk factors included insulin administration within 12 hours and no nutritional therapy. Patients were more likely to have diabetes, to be under a tight glucose control protocol, and to have septic shock. A single episode of hypoglycemia conferred an increased risk of mortality.

Initially, the response to the stress of infection is an increase in glucose turnover, with glucose production often exceeding glucose utilization and resulting in mild hyperglycemia.[75] This early response appears to be mediated by an increase in cortisol, epinephrine, and glucagon. As the infection worsens, the rate of glucose utilization exceeds that of glucose production, and hypoglycemia ensues. This hypoglycemia is secondary to inhibition of gluconeogenesis. Muscle and fat glucose uptake are blocked and may represent a beneficial effect of redirecting glucose to more central tissues. Appropriate management entails (1) treatment of the underlying infection, (2) restoration of normal peripheral perfusion, and (3) infusion of glucose to satisfy tissue demands.

Hepatic and Renal Disease. The liver and kidneys are the only organs that are capable of releasing glucose into the circulation, inasmuch as other tissues generally lack or have minimal amounts of the enzyme glucose-6-phosphatase. Consequently, it is not surprising that patients with hepatic or renal disease are prone to hypoglycemia.[76] Additionally, clearance of insulin is reduced in chronic kidney disease, leading to an increased risk of hypoglycemia. Nevertheless, it is uncommon for hypoglycemia to occur simply as a result of loss of mass or function of these organs, and when it does occur, the cause is usually multifactorial.[76] The large capacities of these organs to release glucose into the circulation and their ability to compensate for each other's shortcomings appear to provide an explanation for this phenomenon.

Normally, the liver accounts for 80% to 85% of all glucose production; it can increase its output (initially mainly by glycogenolysis, later by gluconeogenesis) over a sustained period by 2- to 3-fold. The kidney can also increase its output over a prolonged period by 2- to 3-fold. Studies indicate that the kidney can acutely increase its output to compensate for decreased hepatic glucose production and vice versa, a phenomenon that is referred to as *hepatorenal reciprocity*.[76] Thus, hypoglycemia would be unlikely to develop in patients with hepatic disease until the liver's capacity to produce glucose was reduced beyond the ability of the kidney to compensate.

Liver Disease. Although hypoglycemia has been associated with a wide range of liver diseases (hepatocellular carcinoma, cirrhosis, fatty metamorphosis, toxic and infectious hepatitis, cholangitis, and biliary obstruction), its occurrence is actually uncommon in the absence of other complicating factors (i.e., sepsis or heart failure).[76] The incidence and extent of hypoglycemia in liver disease is variable based on acuity of dysfunction and extent of parenchyma loss. In chronic liver disease associated with hypoglycemia, additional factors, such as malnutrition and infection, are usually involved. A 50% incidence of hypoglycemia was found in patients with liver disease, associated with sepsis and circulatory collapse.[77] In such situations, liver function tests may not parallel the severity of hypoglycemia.

Hyperinsulinemia often accompanies hepatic disease as a consequence of decreased insulin degradation by the liver, but the hypoglycemia of hepatic disease is almost always accompanied by appropriate suppression of plasma insulin concentrations. Only case reports have implicated overproduction of insulin-like growth factors (IGFs) by the liver in primary hepatocellular carcinoma, the neoplasm most frequently associated with fasting hypoglycemia.[78]

Renal Disease. Except in infants, hypoglycemia rarely occurs with acute renal failure. However, with chronic renal failure, hypoglycemia in adult patients without diabetes has an incidence of 1% to 3%.[79,80] It can occur as an isolated event or can be repetitive. In general, neuroglycopenia rather than autonomic symptoms predominates.

The origin of renal hypoglycemia is complex.[79] Many factors, including altered drug metabolism, delayed gastric emptying, malnutrition, infection, dialysis, altered insulin sensitivity and clearance, associated hepatic and cardiac disease, and impaired renal and hepatic glucose production predispose uremic patients to hypoglycemia. Drugs are probably the most common immediate cause. Any drug that can cause hypoglycemia is more likely to do so in a uremic patient because of a prolonged half-life (e.g., insulin, certain sulfonylureas, especially chlorpropamide) or decreased protein binding secondary to hypoalbuminuria. Although hypoglycemia occurs in nondiabetic as well as diabetic patients with renal failure, it is more likely to occur in the latter because of the use of hypoglycemic agents, and because patients with longstanding diabetes have autonomic neuropathy and defects in glucose counterregulation. Malnutrition secondary to anorexia or vomiting, which can reduce hepatic glycogen stores and the availability of gluconeogenic precursors, is a common feature that increases the risk for hypoglycemia.[76]

Several reports suggest that renal failure *per se* predisposes to the development of hypoglycemia.[80] Most evidence points to diminished glucose production rather than increased glucose utilization as a cause of the hypoglycemia. Accompanying malnutrition and acidosis would also contribute to diminished hepatic glycogenolytic and gluconeogenic potential. The expected compensatory increase in renal gluconeogenesis in response to acidosis would be compromised by loss of renal mass and exacerbated by inappropriately high plasma insulin levels caused by reduced renal insulin degradation.

At the present time, no evidence indicates that abnormal counterregulatory hormone responses play a primary role in the pathogenesis of the hypoglycemia associated with renal or liver dysfunction.

Cardiac Failure. Spontaneous hypoglycemia can occur with severe heart failure.[81] The condition has been attributed to a variety of mechanisms, including reduce gluconeogenesis, poor dietary intake, gastrointestinal malabsorption secondary to gut edema, and increased glucose utilization in poorly perfused tissues.

Malnutrition. The prevalence of malnutrition is high among hospitalized patients, and as much as 50% of all patients admitted are malnourished or at risk for malnutrition.[82] The risk of hypoglycemia increases with reduced dietary intake and/or weight loss preceding hospital admission. Patients are more likely to have hypoalbuminemia and comorbid renal failure and anemia. Additionally, hypoglycemia has been reported in eating disorders, particularly anorexia nervosa–restricting type, with a prevalence of 7%.[83]

Hormonal Deficiency. Although cortisol and growth hormone have been demonstrated to contribute independently to glucose counterregulation via their actions to promote glucose production and limit glucose uptake,[19,20] hypoglycemia does not develop in most adults who lack these hormones. Hypoglycemia in adults is more common in secondary adrenal insufficiency (i.e., panhypopituitarism and acute Sheehan syndrome) and patients with T1DM and adrenal insufficiency. However, serious hypoglycemia often develops in infants and children with primary adrenal insufficiency, especially after a period of fasting or during an intercurrent illness.

Patients with longstanding T1DM, adrenalectomized individuals, and those with autonomic neuropathy have impaired catecholamine responses during insulin-induced hypoglycemia,[84] but their increased risk for hypoglycemia can be compensated for by increases in the secretion of other counterregulatory hormones, in particular glucagon. No case of hypoglycemia secondary to isolated catecholamine deficiency have been reported in an adult. It is important to note that acute hypoglycemia can occur during surgical removal of a pheochromocytoma, presumably because of disinhibition of insulin release and abrupt withdrawal of the antiinsulin actions of catecholamines.

Pancreatectomized individuals, patients with longstanding T1DM, and those in whom insulin-requiring diabetes develops as a result of chronic pancreatitis or cystic fibrosis are glucagon-deficient and prone to severe hypoglycemia during treatment for their diabetes. An imbalance between insulin and glucagon secretion (relative glucagon deficiency) has been reported in reactive postprandial hypoglycemia. However, the condition is extremely rare.

Non–Islet Cell Tumors. A large variety of non–islet cell tumors are associated with hypoglycemia.[78] Tumors of mesenchymal origin are generally large and slow-growing, but often malignant. About one third are retroperitoneal, one third are intraabdominal, and one third are intrathoracic. Hypoglycemia may be the presenting sign in about half of patients with IGF-2–secreting tumors, and the treatment is surgical excision. Characteristically, circulating plasma insulin and C-peptide levels are suppressed. Excessive release of IGF-like molecules by the tumor can increase glucose utilization in tissues such as muscle, can suppress endogenous glucose production, and can reduce or overcome the secretion of counterregulatory hormones. Rarely, hypoglycemia results mainly from increased glucose utilization by the tumor.

KEY POINTS

- In nondiabetic individuals, hypoglycemia is rare, with blood glucose levels of 70 mg/dl (≤3.9 mmol/l) or less and 54 mg/dl (≤3.0 mmol/l) or less reported in as few as 1082/100,000 and 910/100,000 emergency medical service encounters, respectively. In hospitalized patients, nondiabetic hypoglycemia accounts for 20% to 30% of hospitalizations with hypoglycemia.

HYPOGLYCEMIA IN APPARENTLY WELL INDIVIDUALS

Endogenous Hyperinsulinism

Failure of insulin secretion to fall in the setting of falling and low blood glucose is abnormal. When the cause of hypoglycemia in an individual without diabetes is not apparent from a detailed history and physical examination, use of diagnostic laboratory studies can prove useful to guide diagnosis.

It is best to obtain laboratory studies during an episode of symptoms.[21] Laboratory evaluation should include: plasma glucose, insulin, C-peptide, β-hydroxybutyrate, proinsulin, and a sulfonylurea and meglitinide screen. If there is concern for endogenous hyperinsulinism, insulin antibodies and/or IGF-2 levels can be obtained but do not require the patient being hypoglycemic at the time of sampling.

If the symptoms occur mostly in the fasting state, the studies should be performed during a fast. This can often be achieved with an observed fast in the clinic or after fasting overnight with subsequent observation in the clinic. If this fails to result in symptomatic hypoglycemia (<55 mg/dL [3 mmol/L]) and there is significant clinical concern, a 72-hour fast should be performed.

The 72-hour fast (Table 38.4) should be supervised to prevent inadvertent caloric consumption or surreptitious drug administration. The patient should be encouraged to be active to simulate real-life situations and prevent sedentary decreases in glucose utilization. Blood samples for plasma glucose, insulin, C-peptide, β-hydroxybutyrate, and proinsulin are generally obtained every 6 hours, and more frequently as the blood glucose drops below 60 mg/dL (3.3 mmol/L). The evaluation is stopped if the blood glucose is less than 55 mg/dL with a history of Whipple's triad, the blood glucose is less than 45 mg/dL (2.5 mmol/L) with symptoms, or 72 hours have elapsed. At this point, a last set of blood samples is obtained, 1 mg of glucagon is administered intravenously, and glucose is measured at 10, 20, and 30 minutes. Finally, the patient is fed. Interpretation of spontaneous or fasted results is given in Table 38.5.

Insulin-Producing Islet Cell Tumors. Insulinoma is a very rare disorder with an incidence of 1 in 250,000 patient-years.[21,85] There is no ethnic predominance, and it is slightly more predominant in women than men. Although insulinomas occur at any age, most occur between 30 and 70 years of age. Approximately 80% of insulinomas are attributed to benign single adenomas, which average less than 2 cm in diameter; 10% are attributed to multiple benign adenomas. Malignant insulinomas are rare (<10% of insulinomas) and are more likely to occur with older age. Insulinoma associated with MEN1 is also rare and is more likely to occur with younger age.

Hypoglycemia in patients with insulinoma is the result of dysregulated insulin release. Insulin release is chaotic, often not appropriately increased by hyperglycemia, and some patients occasionally have impaired glucose tolerance. There is an increased proinsulin-to-insulin ratio and a decreased insulin concentration relative to normal islet tissue. Hypoglycemia occurs as the result of suppression of glucose production rather than increased glucose utilization, inasmuch as plasma insulin concentrations are usually only 50% to 150% above

TABLE 38.4 Sample Protocol for a 72-Hour Fast

Admit before the evening meal. Discontinue all nonessential medications. Insert an intravenous line for blood sampling.

Begin blood sampling (plasma glucose, insulin, C-peptide) just before the meal and continue every 30 minutes for 6 hours and thereafter every 2 to 3 hours.

Sampling should also include sulfonylureas/meglitinides. Additional studies could include morning cortisol, insulin antibodies, and/or IGF-2 based on clinical suspicion and do not necessarily require hypoglycemia.

Patient may consume calorie- and caffeine-lacking liquids and should ambulate.

The fast is ended at 72 hours or earlier if the patient has a plasma glucose level <45 mg/dL (2.5 mmol/L) with symptoms or <55 mg/dL (3.1 mmol/L) with prior Whipple's triad or if 72 hours have elapsed.

At the end of the fast, draw samples for all the above measurements and inject 1 mg of glucagon intravenously and measure plasma glucose at 10, 20, and 30 minutes.

IGF-1, Insulin-like growth factor-1.

TABLE 38.5 Interpretation of a 72-Hour Fast

Diagnosis	Symptoms or Signs	Plasma Glucose (mg/dL)	Plasma Insulin (μU/mL)	Plasma C-Peptide (nmol/L)	β-Hydroxybutyrate	Autoimmune Antibodies	IGF-mediated	Oral Agent Screen
Normal	No	<55	<3	<0.2	>2.7	–	N	–
Endogenous hyperinsulinism	Yes	<55	>3	>0.2	<2.7	–	N	–
Factitious insulin	Yes	<55	>3	<0.2	<2.7	–	N	–
Factitious oral agent	Yes	<55	>3	>0.2	<2.7	–	N	+
Non–islet cell tumor	Yes	<55	<3	<0.2	<2.7	–	↑	–
Autoimmune disorder	Yes	<55	>>3	>>0.2	<2.7	+	N	–

IGF, Insulin-like growth factor; N, normal.

normal levels (but of course inappropriate for the plasma glucose concentration).

Except in late-diagnosed malignant insulinoma cases in which an abdominal mass and signs of metastasis may be present, the physical examination is usually normal. Symptoms are the result of hypoglycemia. Patients with MEN1 also can exhibit symptoms as a result of hypercalcemia and accompanying hyperparathyroidism or other excessive hormone secretions (islet production of adrenocorticotropic hormone, gastrin, and vasoactive intestinal peptide). Frequency and/or severity of hypoglycemia increases over time. Patients with insulinoma can acquire the syndrome of hypoglycemia unawareness.

Although insulinoma has long been classified as one of the so-called fasting hypoglycemias, it is important to remember that such patients can experience hypoglycemia at any time of day, even postprandially. Patients often learn that eating frequently reduces episodes; therefore, weight gain has been observed in about 50% of patients.

There is often a delay in diagnosis. The "gold standard" for diagnosis of insulinoma remains the 72-hour fast. Various tests have been proposed over the years to rule in or rule out the presence of an insulinoma, but all suffer from frequent false positives and false negatives, and none are recommended. Hypoglycemia will develop in essentially all patients with insulinoma during the 72-hour fast; in fact, 75% will become hypoglycemic within 24 hours, and up to 90% over 72 hours.

Only after the diagnosis of hypoglycemia associated with inappropriate hyperinsulinemia has been established biochemically should localization studies be performed. Ninety-nine percent of insulinomas occur within the pancreas. Of the rare insulinomas that are not found in the pancreas, most are found in the wall of the duodenum or gastrosplenic omentum. Pancreatic insulinomas average about 2 cm in diameter and appear with equal frequency in the head, body, and tail.[85] Although approximately 75% to 90% can be identified correctly by palpation at surgery, preoperative localization generally is recommended to minimize manipulation of the pancreas, shorten operative time, avoid blind partial pancreatectomy when the tumor is not palpable, and assist in reoperations when scarring and fibrosis from prior surgery make palpation difficult.[306] Preoperative computed tomography, magnetic romance imaging endoscopic ultrasound, celiac arteriography, and transsplenic portal venous sampling can be used for localization. Currently, preoperative transabdominal ultrasonography followed by intraoperative ultrasonography is considered the most sensitive method.

Surgery is the treatment of choice for insulinoma. Without a diagnosis of MEN1, recurrence after surgery is 7%; with a diagnosis of MEN1, recurrence is as high as 21%. Multiple adenomas, hyperplasia, and malignancy require more extensive surgery. Debulking of a malignant tumor is worthwhile in helping to control hypoglycemia.

Medical therapy is reserved for operated patients with recurrence who refuse another exploration and for those with inoperable malignant tumors. Diazoxide, which inhibits insulin secretion, has been used most widely. The somatostatin analog octreotide has been found to be effective in some patients but must be injected. Continuous glucose monitoring may be useful.

Malignant insulinomas respond poorly to chemotherapy. Survival can be prolonged with multimodal therapy with chemoembolization, radiofrequency ablation, further liver resection, and/or liver transplantation in those without extrahepatic metastases.

Nesidioblastosis. Diffuse islet hyperplasia and/or nesidioblastosis is uncommon in adults (i.e., one to two cases per 100 million patient-years), and congenital hyperinsulinism refers to nesidioblastosis in infants.[21,86] The condition is benign and characterized by diffuse, although not necessarily uniform, hypertrophy and hyperplasia of islet cells (insulin- as well as glucagon- and somatostatin-producing cells), usually associated with differentiation of ductal cells into insulin-producing cells. Adult-onset nesidioblastosis typically occurs around 50 years of age, generally involves the entire pancreas, and is mostly associated with a history of gastric bypass surgery (see "Gastric Bypass Surgery").

It is worth emphasizing that many patients with nesidioblastosis will have a normal 72-hour fast, and their only biochemical abnormality will be postprandial hypoglycemia associated with abnormal plasma insulin and C-peptide levels, which is why it may be preferable to alter the 72-hour protocol and begin the 72-hour fast with a standard meal.

In patients who are suspected of having nesidioblastosis, localization with (^{18}F)-fluoro-3,4-dihydroxyphenylalnine positron emission tomography (^{18}F-DOPA PET) scans and/or the selective calcium infusion procedure, because these tests will confirm the diagnosis of pancreatic hyperinsulinism as the probable cause of the hypoglycemia when reliable localization procedures are negative.

Surgery is the treatment of choice for nesidioblastosis. In patients with nesidioblastosis, gradient-directed resection can result in cure of hypoglycemia. Treatment generally consists of 60% to 90% distal pancreatectomy. Half of patients undergoing this procedure are cured of hypoglycemia and are normoglycemic.

Gastric Bypass Surgery. Accompanying the rapid increase in obesity is an increase in the number of bariatric surgical procedures performed. Recently, accumulating reports are demonstrating an increase in severe postprandial hypoglycemia following gastric bypass surgery. The etiology is not well understood. Although the disorder was initially thought to represent a version of the adult nesidioblastosis syndrome, subsequent analysis of the pancreata have revealed that this may be caused by a combination of gastric dumping and inappropriately increased insulin secretion.[21,87] Patients with this syndrome have shown exaggerated GLP1 and insulin responses to a mixed meal. There is a strong female preponderance, and this condition can develop months or even years after bypass surgery is performed.

Treatment for hypoglycemia has proved to be problematic. Dietary changes, acarbose, diazoxide, and octreotide may alleviate symptoms. If a patient fails to respond to these measures, partial pancreatectomy is recommended.

Autoimmune Hypoglycemia. Autoimmune hypoglycemia is a very rare diagnosis caused by autoantibodies against insulin itself or against the insulin receptor. Both are rare and can produce fasting, as well as postprandial, reactive hypoglycemia—primarily the former.[21,88]

Insulin Autoimmune Syndrome. Insulin autoimmune syndrome (Hirata syndrome) is described as hyperinsulinemic hypoglycemia with high concentrations of insulin autoantibodies. It is classically described in individuals without exposure to exogenous insulin but has also been described in individuals treated with insulin. It has been best reported in patients of Japanese or Korean ethnicity. It can be described in isolation and has also been included in type 3A or type 4 autoimmune polyendocrine syndromes. The use of certain drugs (i.e., methimazole, carbimazole, alpha-lipoic acid) has been implicated in initiating the syndrome.

Hypoglycemia occurs because dissociation of insulin from the antibodies causes prolonged hyperinsulinemia. Postprandial hypoglycemia is more common with this syndrome than is fasting hypoglycemia. Circulating insulin levels are increased, and C-peptide levels may not be suppressed because they are in patients who are taking insulin surreptitiously. Unlike the other syndrome of autoimmune hypoglycemia, the course of this condition is benign and self-limited, with remission usually occurring within 1 year. Simple interventions such as frequent small meals with cornstarch and a low content of simple sugars often suffice. Rarely, glucocorticoids, somatostatin analogs, diazoxide, and immunosuppressive agents are used. CGM may be useful.

Antiinsulin Receptor Antibodies. This is an even more rare condition.[89] Hypoglycemia that develops as a result of antibodies directed against the insulin receptor has been reported. These antibodies act as agonists and produce hypoglycemia similar to insulin. Most patients have evidence of other conditions associated with altered autoimmunity. Some patients have developed severe insulin resistance as a result of the antibodies blocking the insulin receptor before the antibodies became agonists. Low circulating insulin and C-peptide levels, normal IGF-1, and appropriate counterregulatory hormone responses are characteristic in this condition.

With time, antibody titers appear to decline, and most patients have remission. Aggressive therapy is appropriate because of the severity of the hypoglycemia. Treatment with high-dose glucocorticoids, plasmapheresis, and alkylating agents has been attempted, with some success.

Factitious Hypoglycemia. Factitious hypoglycemia refers to a situation in which an individual intentionally attempts to create the impression of the presence of a hypoglycemic disorder, typically by using sulfonylureas or insulin.[21,90] This includes diabetic individuals who falsify their self–glucose monitoring or who overdose or underdose themselves to intentionally create the impression of better than actual glycemic control or brittle diabetes, as well as cases of child abuse. Generally excluded are inadvertent sulfonylurea ingestion (see "Drug-Induced Hypoglycemia"), homicides, suicide attempts, and substance abuse in which the additional use of insulin or sulfonylureas is intended to "obtain a high," rather than to create the impression of a hypoglycemic disorder. These situations nevertheless can present diagnostic challenges.

The condition is probably more common than this figure would indicate, because most cases go unreported.[91] In nearly all instances, the individuals had diabetes; had been a relative, spouse, or friend of a diabetic patient; or were in a medical or paramedical profession. Thus, factitious hypoglycemia should be suspected in individuals or their relatives who have unexplained hypoglycemia and knowledge of and/or access to insulin, sulfonylureas, or meglitinides.

Those in whom hypoglycemia develops as a result of surreptitious insulin injection will have inappropriate plasma insulin levels and a suppressed plasma C-peptide level. This finding is diagnostic. Patients taking sulfonylureas or a meglitinide will have inappropriate plasma insulin and C-peptide levels because of stimulation of endogenous insulin secretion, and this pattern will mimic that seen in patients with insulinoma. A urine or plasma assay for sulfonylureas and meglitinides is diagnostic. Many patients who are documented biochemically to have self-induced hypoglycemia will adamantly deny inducing the condition when confronted with the evidence. Nevertheless, psychological counseling with other physicians is warranted to prevent subsequent episodes or substitution of other potentially self-destructive behaviors.

Reactive Hypoglycemia. Reactive hypoglycemia refers to hypoglycemia that occurs after meals.[92] An OGTT is a test for diabetes mellitus and is inappropriate to use to evaluate the presence of reactive hypoglycemia. Generally, a standardized mixed meal is used for diagnosis, but some contend that hypoglycemia should be assessed during "normal" life. If the diagnosis is confirmed, one should exclude impaired glucose tolerance or mild diabetes, renal glycosuria, peptic ulcer disease, and other gastrointestinal disorders. Alimentary hypoglycemia can occur 2 to 4 hours after meal ingestion in patients who have undergone various abdominal procedures (i.e., gastrectomy or vagotomy) or with altered gastric motility, for example. Rapid gastric emptying and glucose absorption, which cause hyperglycemia and release of gut insulin secretagogues, result in excessive secretion of insulin; the biological actions of insulin to suppress endogenous glucose production and to stimulate tissue glucose uptake persist after the carbohydrate in the meal has been absorbed. This imbalance leads to postprandial hypoglycemia. GLP1, high insulin sensitivity, defects in counterregulation, and abnormal glucagon response are possible mechanisms. Treatment involves prevention of rapid absorption of large amounts of carbohydrate, frequent small meals, avoidance of large amounts of simple sugars, addition of fiber to the diet, and use of α-glucosidase inhibitors.

Pregnancy. Despite a decrease in insulin sensitivity and an increase in glucose turnover to accommodate the needs of the fetus, mean plasma glucose levels are normally 10% to 20% lower during the third and second trimesters of pregnancy, respectively.[93] Nevertheless, a great number of metabolic changes occur during pregnancy that make a woman more vulnerable to hypoglycemia. Any condition that can cause hypoglycemia in a nonpregnant woman can do so in a pregnant woman. First-trimester hypoglycemia is frequent in women treated with insulin, and one in four maternal deaths have been attributed to hypoglycemia ("dead in bed syndrome").[13,94] Balancing the priorities of glucose control in pregnancy for maternal and fetal outcomes, without excessive hypoglycemia, remains a challenge.

KEY POINTS

- Insulinoma is a very rare disorder occurring with an incidence of 1 in 250,000 patient-years. Approximately 80% of insulinomas are attributed to benign single adenomas; 10% are attributed to multiple benign adenomas. Malignant insulinomas are rare.

NEONATAL HYPOGLYCEMIA

Hypoglycemia is an important cause of morbidity in children.[95] There is a high incidence of neurodevelopmental delays, making the diagnosis critical.

Children's brains have a three times higher glucose utilization rate per kilogram body weight than adults. Thus, in situations such as hyperinsulinism or disorders of fatty acid oxidation, which are hypoketotic, there are not sufficient levels of alternate energy fuels for the brain, and the risk of brain failure increase. Two- to three-day-old neonates, infants, and children have similar metabolic defenses against hypoglycemia as adults. However, because of their larger brains, blood glucose drops more quickly, and hyperketonemia develops more rapidly.

In neonates aged older than 48 hours, infants, and children, blood glucose levels are generally the same as those observed in adults. In the neonate who is less than 48 hours old, glucose often decreases just after birth below levels observed in older infants and children. Neonates at risk of hypoglycemia include those who are large for gestational age, experienced perinatal stress, had premature or postmature delivery, have a diabetic mother, or have a family history of genetic hypoglycemia. Neonates with severe hypoglycemia, which is defined as an inability to consistently maintain blood glucose greater than 50 mg/dL for the first 48 hours of life and greater than 60 mg/dL thereafter, family history of genetic hypoglycemia and congenital syndromes should also be evaluated.

Numerous pathologic conditions can cause neonatal hypoglycemia (Table 38.6). It should be noted that, although inborn errors of metabolism and hormonal deficiencies can be responsible for hypoglycemia in neonates, adolescents and adults may present with hypoglycemia arising from such defects without prior diagnosis. However, these cases are less frequent and severe than in neonates.

TABLE 38.6 Causes of Neonatal Hypoglycemia and Inborn Errors of Metabolism

Acquired hyperinsulinism
- Maternal diabetes
- Intravenous glucose during labor and delivery
- Maternal oral hypoglycemic agents, propranolol, labetalol
- Low birth weight, prematurity, preeclampsia
- Neonatal sepsis, perinatal asphyxia

Counterregulatory hormone deficiency
- Hypopituitarism
- Growth hormone deficiency
- Adrenal insufficiency

Congenital hyperinsulinism
- Beckwith–Wiedemann syndrome
- Adenosine triphosphate–sensitive channel hyperinsulinism
- Sur-1 encoded by *ABCC8*
- Kir6.2 encoded by *KCNJ11*
- Glucokinase encoded by *GCK*
- Glutamate dehydrogenase encoded by *GLUD-1*
- Mitochondrial enzyme short-chain-3-hydroxyacety1-cort dehydrogenase encoded by *HAD1-1S*
- Disorders of glycosylation

Mitochondrial fatty acid oxidation disorders

Gluconeogenic disorders—fructose-1-6-biphosphate deficiency

Glycogen storage disorders
- Glucose-6-phosphate deficiency
- Glycogen synthase deficiency

Galactosemia

Maple syrup urine disease

Propionic acidemia

TABLE 38.7 Blood and Urine Tests for Metabolic and Endocrine Causes of Neonatal Hypoglycemia and Inborn Errors of Metabolism

Blood Glucose
- Lactate, pyruvate, free fatty acids, glycerol, ketones
- Amino acids
- Carnitine
- Acyl carnitine
- Insulin, C-peptide, proinsulin:insulin ratio, growth hormone, cortisol, thyroid hormones, thyroid-stimulating hormone (TSH)
- Growth hormone, cortisol, thyroid hormones, TSH
- Galactosemia screen

Urine
- Ketones
- Organic acids (3-hydroxybutyrate)
- Carnitine

Diagnostic Investigation of an Infant with Persistent Hypoglycemia. Because of the wide range of conditions that can cause hypoglycemia in an infant, a variety of blood and urine tests can be helpful in identifying metabolic and endocrine causes of the disorder (Table 38.7).[95]

It is surprising that plasma insulin levels often are not strikingly elevated in the congenital hyperinsulinism syndromes. Similar to insulinomas, plasma insulin levels often are modestly increased but are inappropriately raised in relation to the prevailing hypoglycemia. However, measurement of free fatty acids and β-hydroxybutyrate levels reveals dramatic suppression and evidence of significant insulin action. An increase in plasma glucose greater than 30 mg/dL (1.7 mmol/L) following a glucagon challenge test is also supportive of the diagnosis of relative hyperinsulinism. Genetic testing is now widely available for identification of genes associated with congenital hyperinsulinism, both monogenic and syndromic congenital forms.

Congenital Hyperinsulinism. The most common causes of persistent neonatal hypoglycemia are the congenital hyperinsulinism syndromes. Although they are rare overall, the incidence is increased in consanguineous families. These syndromes have been estimated to occur at a rate of approximately 1:50,000 births worldwide. The pathophysiology and the molecular and genetic bases for congenital hyperinsulinism have been reviewed by De Leon and Stanley.[96] Of these, the most frequently occurring involve loss-of-function mutations in the pancreatic β cell adenosine triphosphate–dependent potassium (K_{ATP}) channel, Kir6.2 channel, and Sur-1 receptor.

The clinical presentation of infants with congenital hyperinsulinism may be varied but typically involves prolonged and severe hypoglycemia with lethargy, seizures, and apnea, and babies are often large for gestational age. Typically, hypoglycemia occurs in the fasting or postprandial state, and these infants require large rates of glucose infusion greater than 10 mg/kg/min to prevent severe hypoglycemia.

Initially, treatment consists of diazoxide, which is a K_{ATP} channel agonist and has a suppressive effect on insulin secretion. If diazoxide does not produce a clinical response, octreotide has been used to suppress insulin release. However, in children who are unresponsive to medical therapy, the next treatment is surgery. This can comprise a local resection or a near-total (98%) pancreatectomy, depending upon the presence of focal or diffuse disease. The application of ^{18}F-DOPA PET scans to differentiate focal from diffuse pancreatic involvement in the congenital hyperinsulinism syndromes has provided a clinical breakthrough in the management of these children.

Mitochondrial Fatty Acid Oxidation Disorders. Eleven different mitochondrial fatty acid oxidation disorders can present with fasting (hypoketotic) or postprandial hypoglycemia.[97] Hepatic oxidation of fatty acids produces energy and acetyl-CoA, both of which are essential for gluconeogenesis. Additionally, fatty acid oxidation is required for hepatic ketone production. However, because of specific defects in mitochondrial fatty acid oxidation, gluconeogenesis is reduced, and this results in hypoglycemia and a lack of ketone bodies. The combination creates a scenario whereby the brain becomes starved of glucose and its primary alternative substrate (ketones), which creates conditions for severe neurologic consequences. Plasma membrane carnitine transporter deficiency is an autosomal recessive disorder that occurs in approximately 1:40,000 infants. Low plasma carnitine and acyl carnitine are indicative of this disorder, and treatment with dietary carnitine prevents hypoglycemia. Carnitine palmitoyl transferase 1 and 2 (CPT-1 and CPT-2) deficiencies can present as severe, life-threatening events that require frequent feeding and supplementation with dietary medium-chain triglycerides and L-carnitine (CPT-2 deficiency). Unfortunately, the most severe form of CPT-2 deficiency can present soon after birth and can be fatal. Medium-chain acetyl-CoA dehydrogenase deficiency is the most common fatty acid oxidation defect and is inherited as an autosomal recessive trait. Hypoglycemia usually occurs during fasting and conditions of stress such as viral illness. The presentation can be serious, with vomiting, apnea, coma, and encephalopathy. It has been estimated that, if left undiagnosed, up to 25% of children may die during the presenting event. Blood tests demonstrate elevated medium-chain acylcarnitine. As with other mitochondrial fatty acid oxidation disorders, the enzyme deficiency can be demonstrated diagnostically in fibroblasts. Treatment consists of avoidance of fasting and precipitation of attacks that could lead to neurologic defects and even death. Thus, frequent meals, bedtime snacks, uncooked cornstarch (to avoid nocturnal hypoglycemia), and carnitine supplementation have been used successfully in these children.

Very long chain acyl-CoA dehydrogenase (VLCAD) and short-chain acyl-CoA dehydrogenase (SCAD) deficiencies can present with serious, sometimes fatal, episodes of hypoglycemia and metabolic acidosis. These defects are also associated with cardiomyopathy (VLCAD), hepatomegaly, and neurologic defects (SCAD). Treatment involves avoidance of fasting and maintenance of glucose levels during stress, with frequent meals enriched with carbohydrate and medium-chain triglycerides. Carnitine supplementation in these conditions is not recommended (VLCAD) or has limited applicability (SCAD).

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) and mitochondrial trifunctional protein deficiency are also autosomal recessive disorders. Both conditions can present with severe hypoglycemia, encephalopathy, neurologic complications, and death. Both conditions can result in peripheral neuropathy, and LCHAD deficiency can result in pigmentary retinopathy and blindness. Treatment is similar to that provided for the above fatty acid oxidation defects. Long-chain ketothilase and 2-4-dienoyl-CoA reductase deficiency are very rare conditions.

Glycogen Storage Diseases. All glycogen storage diseases are caused by an inability to use or store glycogen.[98] Glycogen synthase deficiency, glucose-6-phosphatase deficiency, and glycogen debrancher deficiency often show in the neonatal period with hypoglycemia. Additionally, glycogen-phosphorylase deficiency can present later in childhood. Of the disorders, glucose-6-phosphate deficiency is associated with the most severe hypoglycemic phenotype. Prevention of hypoglycemia is the same for all of the glycogen storage disorders. Prevention of hypoglycemia during stress, exercise, and during the nighttime hours includes consuming frequent carbohydrate-containing meals, as well as bedtime snacks. Intravenous glucose may be necessary to maintain plasma glucose levels above 70 mg/dL (3.9 mmol/L) under intense stress. Lysosomal acid α-glucosidase deficiency can be treated with enzyme replacement therapy using recombinant alglucosidase alfa (Lumizyme), which degrades lysosomal glycogen.

CONCLUSION AND FUTURE DIRECTIONS

Hypoglycemia remains a significant problem for those with diabetes. Future advancements in technology, including increasingly less burdensome CGM and progressively more complex integration of CGM with insulin delivery (perhaps combined with other hormone therapy), are likely to result in significant improvements in quality of life for those who suffer from hypoglycemia. There remains much to learn about the concept of HAAF and how the underlying physiology can be used to direct therapies against this challenge. Lastly, elucidating the relationship between hypoglycemia and cardiovascular risk is critical, as is an understanding of which populations are vulnerable to this association.

Future Perspectives, 686

The discovery of insulin in the summer of 1921 by Frederick Banting, Charles Best, James Collip, and J. J. R. Macleod at the University of Toronto and its first therapeutic use on January 11, 1922, at the Toronto General Hospital, stand as one of the greatest achievements of contemporary medicine.[1] By providing life-sustaining therapy for a previously fatal wasting condition, the discovery of insulin dramatically shifted the prognosis of type 1 diabetes to that of a chronic disease that could be treated but not cured. Research since then has shown that achieving and maintaining near-euglycemia can prevent and/or slow the progression to microvascular complications, and to some degree macrovascular disease. The Diabetes Control and Complications Trial (DCCT) and other studies evaluating optimization of glycemic control have provided compelling evidence for the benefits of tight glycemic control.[2-5] However, outside of a research setting, normalizing and maintaining near-euglycemia can be a daunting task, and targets are not achieved by the majority of people with type 1 diabetes.[6] Newer insulins and technologies have made this goal increasingly possible. But the clinical practice of type 1 diabetes management must be able to provide the support, knowledge, and education patients need to adopt and implement these new tools. An interdisciplinary healthcare team consisting of individuals such as physicians, diabetes educators, dietitians, mental health providers, pharmacists, and anyone else the patient needs for support is key to providing the resources a patient may need. In this chapter, we review the essential elements of this approach to comprehensive care of patients with type 1 diabetes.

GOALS OF MANAGEMENT

The overriding goal in the management of type 1 diabetes is the optimization of the patient's quality of life through the prevention and amelioration of the acute and chronic complications that are associated with this disease. In the modern era, a substantial body of epidemiologic and experimental evidence has established the relationship between diabetic complications and hyperglycemia (see Chapter 42). In particular, the findings of the DCCT have had an enormous impact on the management of type 1 diabetes and warrant review before discussion of specific therapeutic goals.

The DCCT was a multicenter, National Institutes of Health–funded randomized, controlled clinical trial initiated in 1982 that was designed to assess whether intensive treatment with the goal of maintaining near-normal blood glucose concentrations could reduce the frequency and severity of diabetic complications.[2] A total of 1441 patients with type 1 diabetes from the United States and Canada participated in the study and made up two cohorts: a primary prevention cohort of 726 subjects with no retinopathy at baseline and a duration of diabetes of 1 to 5 years, and a secondary intervention cohort of 715 individuals with mild retinopathy and duration of diabetes of up to 15 years. Participants were randomly assigned to receive either the conventional therapy of the day (one or two injections of insulin per day) or intensive therapy (either three or more insulin injections or continuous subcutaneous insulin infusion (CSII) by external pump, with frequent blood glucose monitoring). After a mean of 6.5 years of follow-up, mean glycosylated hemoglobin (A_{1c}) was 7.2% in the intensive therapy arm and 9.0% in the conventional treatment arm. The intensive therapy group showed a relative risk reduction of 76% (95% confidence

KEY POINTS

- The goal of type 1 diabetes management is the achievement of sustained euglycemia, with avoidance of hypoglycemia, through the physiologic replacement of insulin.
- Intensive insulin therapy, assisted by technology, is recommended for all patients with type 1 diabetes.
- Intensive insulin therapy can reduce the risk for microvascular and macrovascular complications in type 1 diabetes.

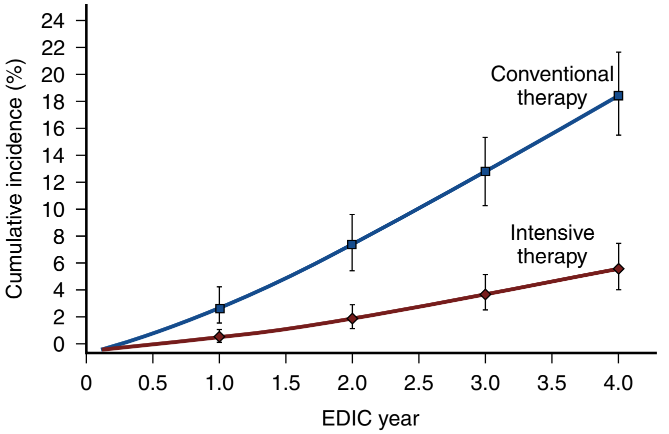

Fig. 39.1 Cumulative incidence of further progression of retinopathy during the Epidemiology of Diabetes Interventions and Complications study in the former conventional therapy and intensive therapy cohorts from the Diabetes Control and Complications Trial (DCCT). Data are based on regression analysis adjusted for the level of retinopathy at the end of the DCCT, whether patients received therapy as primary prevention or as secondary intervention, and for the duration of diabetes and the glycosylated hemoglobin value on enrollment in the DCCT. (From Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group. Retinopathy and nephropathy in patients with type 1 diabetes four years after a trial of intensive therapy. *N Engl J Med.* 2000;342:387.)

interval [CI]: 62%–85%) for the development of retinopathy and a 54% relative risk reduction (95% CI: 39%–66%) for progression of retinopathy. Similarly, intensive therapy was associated with relative risk reductions of 39% (95% CI: 21%–52%) for the development of microalbuminuria (defined as urinary albumin excretion >40 mg per 24 hours) and 54% (95% CI: 19%–74%) for progression to albuminuria (urinary albumin excretion >300 mg per 24 hours). The incidence of clinical neuropathy was also decreased in the intensive group, with a relative risk reduction of 60% (95% CI: 38%–74%). Thus, the DCCT provided conclusive evidence that improved glycemic control with intensive therapy can reduce the incidence of microvascular complications (primary prevention) and can slow the progression of established microvascular disease (secondary intervention).

The benefits of near-normal glycemic control were found to persist for many years after the DCCT, according to data from the follow-up study, the Epidemiology of Diabetes Interventions and Complications (EDIC).[7] In the ongoing EDIC observational study, a large cohort consisting of more than 95% of the DCCT participants (n = 1375) has been followed since the completion of the original trial and has been studied by using an intention-to-treat approach based on the original randomization in the DCCT. The mean A_{1c} levels of the former intensive treatment cohort and the former conventional therapy group have converged ($A_{1c} \approx 8\%$) over the course of the EDIC study and were no longer significantly different at 5 years post-DCCT. Remarkably, however, despite similar glycemic control, the former intensive therapy group continued to display reduced risk for both new retinopathy and new nephropathy at 4 years and 7 to 8 years post-DCCT, respectively, compared with the group of patients who were randomized originally to conventional therapy (Fig. 39.1).[7,8] With continued follow-up in the EDIC study, the former intensive therapy group has exhibited further benefits, including risk reduction for the development of impaired glomerular filtration and hypertension.[9,10] These persistent beneficial effects of previous near-normal glycemic control have extended the results of the DCCT and demonstrate that intensive treatment should be initiated as early as is safely possible in the management of type 1 diabetes.

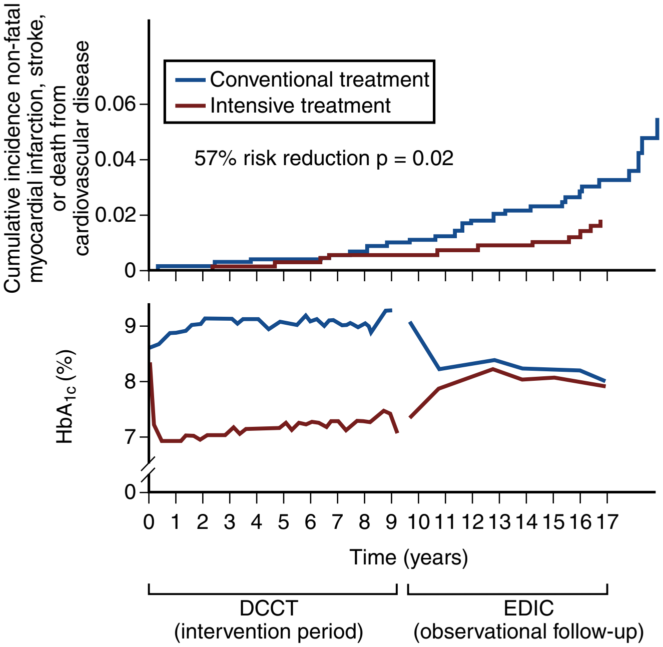

Fig. 39.2 Differences in glycosylated hemoglobin *(lower panel)* and cardiovascular event rates *(upper panel)* over time between the intensive and conventional diabetes treatment arms of the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications study cohort. (From Retnakaran R, Zinman B. Type 1 diabetes, hyperglycaemia and the heart. *Lancet.* 2008;371:1790–1799.)

Although the DCCT conclusively documented that intensive therapy can reduce the risk for microvascular complications, the effect on macrovascular disease was initially less clear. By the end of the DCCT, the intensive therapy arm displayed a relative risk reduction of 34% (95% CI: 7%–54%) for the development of elevated low-density lipoprotein (LDL) cholesterol levels. Nevertheless, even though intensive therapy was associated with a 41% relative risk reduction (95% CI: –10% to 68%) for macrovascular complications, this difference was not statistically significant.[2] It is important to note, however, that the macrovascular benefits derived from near-normal glycemic control in the former intensive treatment arm of the DCCT have emerged over time in the EDIC study. Indeed, after a mean follow-up of 17 years, it was observed that intensive therapy during the DCCT had reduced the subsequent risk for any cardiovascular disease (CVD) event by 42% (95% CI: 9%–63%; $P = 0.02$) and the risk for nonfatal myocardial infarction, stroke, or cardiovascular death by 57% (95% CI: 12%–79%; $P = 0.02$) (Fig. 39.2).[11] This remarkable risk reduction was largely explained by differences in the updated mean A_{1c} during the DCCT. Furthermore, the reduction in CVD events was consistent with earlier observations that intensive therapy had reduced the progression of atherosclerosis (as measured by carotid artery intima media thickness [IMT]) and the prevalence of coronary artery calcification (CAC) during the DCCT/EDIC study, with both effects associated with the reduction in mean A_{1c} achieved with intensive therapy.[12,13] Thus, intensive therapy (with associated reduced glycemic exposure) during the mean 6.5 years of the DCCT first significantly reduced surrogate measures of atherosclerotic disease (carotid IMT, CAC) and later reduced clinical CVD events over the course of the EDIC study (Fig. 39.3). These data demonstrate that the long-term risk associated with past glycemic exposure extends to both microvascular and macrovascular disease.[14] Indeed, it has been hypothesized that glycemic exposure early in the course of the disease may have an effect of metabolic imprinting (referred to as "metabolic memory") that contributes to future risk for vascular complications.[11] Taken together, these data

further underscore the importance of initiating intensive therapy as early as safely possible in the management of type 1 diabetes.

Overall, the DCCT helped to clarify the relationship between A_{1c} and diabetic complications. For every 10% reduction in A_{1c}, the risk for developing retinopathy was reduced by approximately 45%.[15] Moreover, a continuous curvilinear relationship was observed between A_{1c} and the incidence of retinopathy, the risk for progressive retinopathy being decreased substantially at A_{1c} levels below 7%. Although the risk for progressive retinopathy was further reduced at A_{1c} concentrations below 7% (i.e., no threshold effect), this benefit was achieved at the cost of a significantly increased risk for hypoglycemia, given an observed continuous and inverse relationship between hypoglycemic risk and A_{1c} (Fig. 39.4). However, the DCCT was performed before the advent of some of the newer analog insulins, continuous glucose monitoring (CGM), or hybrid closed loop (HCL) systems, which are associated with lower rates of hypoglycemia than were seen in the DCCT.

Weight gain was an additional undesired impact of intensive therapy in a subset of individuals.[16] Thus, the DCCT firmly established the importance of glycemic control in the management of type 1 diabetes, demonstrated the feasibility of intensive therapy in improving glycemic control, and identified the limitations imposed on such control by hypoglycemia and weight gain. In doing so, this study has provided a framework for current treatment goals.

KEY POINTS

- Intensive insulin therapy can reduce the risk for microvascular and macrovascular complications in type 1 diabetes.

Glycemic Goals

On the basis of the findings of the DCCT/EDIC and other studies, the ultimate objective in the treatment of type 1 diabetes is metabolic normalization, that is, the achievement of sustained glycemic control as close to normal as possible and the avoidance of hypoglycemia. The glycemic target should be individualized based on the duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness,

TABLE 39.1 American Diabetes Association Recommendations for Glycemia Treatment Targets in Nonpregnant Adults With Diabetes

Glycemic Parameter	Target
A_{1c}	<7.0%
Preprandial plasma glucose	70–130 mg/dL
Postprandial plasma glucose	<180 mg/dL
Time in range	>70%
GMI	<7%
CV	<36%

Goals are individualized for a given patient.

and individual patient considerations and may change over time. Goals should be achieved in conjunction with an understanding of the person's psychosocial needs and a reduction in diabetes distress if elevated. In this context, the 2021 American Diabetes Association (ADA) treatment guidelines suggest the following therapeutic targets for nonpregnant adults with type 1 or type 2 diabetes: (1) A_{1c} less than 7.0% (referenced to nondiabetic range 4.0%–6.0%); (2) preprandial plasma glucose 70 to 130 mg/dL; and (3) peak postprandial plasma glucose less than 180 mg/dL (Table 39.1).[17] Achievement of lower A_{1c} levels than the goal of 7% (53 mmol/mol) may be acceptable, and even beneficial, following discussion between the person with diabetes and his or her healthcare professional, if it can be achieved safely without significant hypoglycemia or other adverse effects of treatment. Less stringent A_{1c} goals (such as <8% [64 mmol/mol]) may be appropriate for individuals with limited life expectancy, or where the harms of treatment are greater than the benefits.[18]

An alternative to the measurement of A_{1c} is an assessment of the Glucose Management Index (GMI) and Time in Range (TIR) from CGM data. In this setting, as well as the GMI goal of 7% (53 mmol/mol), a parallel goal would be a TIR of greater than 70% with time below range less than 4%. Fig. 39.5 shows the ambulatory glucose profile, which is the preferred method for evaluating data from continuous glucose monitors. In addition to TIR and GMI, it also provides an assessment of time above and below ranges, as well as glycemic variability.[19]

KEY POINTS

- The ultimate objective in the treatment of type 1 diabetes is the achievement of sustained glycemic control as close to normal as possible and the avoidance of hypoglycemia.

ACUTE COMPLICATIONS

The major acute complications of type 1 diabetes are ketoacidosis and hypoglycemia. These topics are discussed in detail in Chapters 37 and 38, respectively. The risk for these acute complications can be reduced through the judicious use of insulin therapy. Specifically, the risk for ketoacidosis can be reduced through appreciation of the concept that patients with type 1 diabetes require insulin therapy at all times. Appropriate management of special situations, such as intercurrent illness, requires adherence to this principle (see the section entitled "Adjustment of Insulin Therapy in Special Situations").

As was observed in the DCCT (see Fig. 39.2B), tight glycemic control typically is associated with an increased risk for hypoglycemia, although this may be mitigated through use of current technology. Regardless, patients therefore must be educated about the recognition of hypoglycemic symptoms and the use of appropriate treatment measures when such symptoms arise. Patients are advised to keep rapidly absorbable sources of carbohydrate, such as glucose tablets, close at hand at all times. In general, 15 g of carbohydrate is needed to increase blood glucose levels by approximately 38 mg/dL within 20 minutes.[20,21] Besides glucose tablets, other treatments that provide a similar amount of glucose include (1) 15 mL (1 tablespoon) or three packets of table sugar dissolved in water, (2) 175 mL (4 ounces) of juice, and (3) 15 mL (1 tablespoon) of honey. In addition, patients with type 1 diabetes should have an emergency glucagon kit that can be administered intranasally, subcutaneously, or intramuscularly. Both the patient and his or her family members should be trained in the use of glucagon as a means of rapidly increasing blood glucose concentration if the patient is severely hypoglycemic and unable to safely consume oral carbohydrate.

CHRONIC COMPLICATIONS

The chronic microvascular complications of type 1 diabetes include retinopathy, neuropathy, and nephropathy (discussed in Chapters 43, 44, and 45, respectively). To reduce the impact of these complications, management strategies include regular surveillance for early detection of complications and intensive diabetes management for both primary prevention and secondary intervention, as demonstrated in the DCCT.

Macrovascular disease, as manifested by cerebrovascular, peripheral vascular, and coronary artery disease, is a major chronic complication of type 1 diabetes (discussed in Chapter 46). Regular surveillance for vascular disease and management of cardiovascular risk factors is essential. In particular, modification of reversible cardiovascular risk factors, such as hypertension, dyslipidemia, and cigarette smoking, is an important management goal. The 2021 ADA treatment guidelines suggest a target blood pressure of less than 140/90 mm Hg in patients with diabetes and less than 130/80 mm Hg in certain higher-risk individuals. In addition, the following treatment targets for lipids are recommended: LDL less than 100 mg/dL (or lower if known CVD), triglycerides less than 150 mg/dL, and high-density lipoprotein (HDL) greater than 40 mg/dL in men and HDL greater than 50 mg/dL in women.[17]

QUALITY OF LIFE

Type 1 diabetes is a chronic condition that requires a complex healthcare strategy that demands significant patient effort through frequent insulin injections or insulin pump therapy, regular self-monitoring of blood glucose (SMBG) or CGM, and constant attention to nutrition and physical activity. As such, effective management requires that the patient take responsibility for his or her care. In this context, it should be noted that psychosocial factors as well as social determinants of health all play a large role in terms of a patient's ability to manage his or her diabetes.[22] Recognition of these concepts at all times by the healthcare team will facilitate the success of treatment initiatives, as well as the need to involve mental health providers in patient care. Additionally, the concept of diabetes distress[23] is one that healthcare providers should be aware of, and reducing distress should be part of any treatment plan.

TEAM APPROACH TO MANAGEMENT

Given the complexity of modern treatment regimens, comprehensive care for patients with type 1 diabetes is best accomplished through a team approach. The core members of the diabetes healthcare team include the patient, the primary physician, a diabetes nurse educator, and a registered dietitian. Other individuals participating in the

GLUCOSE STATISTICS AND TARGETS

26 Feb 2019–10 Mar 2019 **13 days**
% Time CGM is Active **99.9%**

Glucose Ranges	**Targets** [% of Readings (Time/Day)]
Target Range 70–180 mg/dL	Greater than 70% (16h 48min)
Below 70 mg/dL	Less than 4% (58min)
Below 54 mg/dL	Less than 1% (14min)
Above 180 mg/dL	Less than 25% (6h)
Above 250 mg/dL	Less than 5% (1h 12min)

Each 5% increase in time in range (70–180 mg/dL) is clinically beneficial.

Average Glucose	**173 mg/dL**
Glucose Management Indicator (GMI)	**7.6%**
Glucose Variability	**49.5%**

Defined as percent coefficient of variation (%CV); target ≤36%

TIME IN RANGES

Very High (>250mg/dL)	**20%** (4h 48min)
High (181–250mg/dL)	**23%** (5h 31min)
Target Range (70–180 mg/dL)	**47%** (11h 17min)
Low (54–69 mg/dL)	**4%** (58min)
Very Low (<54 mg/dL)	**6%** (1h 26min)

patient's care may include a pharmacist, a medical social worker, a mental health specialist, a foot care specialist, an ophthalmologist, and other medical specialists such as cardiologists, nephrologists, and neurologists. At all times, the central role of the patient as a member of the healthcare team must be recognized. Accordingly, the efforts of the healthcare team should always be pursued from a patient-centered perspective. Inherent in this approach is the central importance of patient education, as the patient's active participation in his or her care demands an understanding of the issues associated with the treatment plan. As will be discussed in later sections of this chapter, the patient needs to be equipped with the knowledge and skills required for activities such as SMBG (with fingersticks or a continuous glucose monitor), glycemic pattern management, estimation of the carbohydrate content of meals, insulin dose adjustment, and appropriate insulin administration.

MONITORING

Type 1 diabetes is a chronic condition involving complex treatment regimens and multiple management goals. As such, regular monitoring of patient status is an essential component of comprehensive care. Patient monitoring in type 1 diabetes addresses two fundamental issues. First of all, frequent acute assessment of metabolic status guides adjustment of the treatment regimen, which, by nature, must be dynamic and able to accommodate day-to-day physiologic variability. Second, regular surveillance of both important clinical outcomes and associated surrogate markers allows for the detection and treatment of chronic complications and attendant comorbidities.

Glycemic Control

Regular monitoring of glycemic status by both patients and healthcare providers is fundamental to diabetes care. Glycemic monitoring involves frequent, acute measurement of blood glucose levels by the patient and periodic evaluation of chronic glycemic control through laboratory measurement of markers of glucose concentration such as A_{1c}, as well as assessments of TIR and GMI for those on CGM.

Acute Measurement of Glycemic Control. SMBG by patients is an invaluable tool that has empowered patient-driven management of type 1 diabetes, although it is increasingly being supplanted by use of CGM. SMBG involves using a small lancet to draw a drop of capillary blood from the fingertip. The patient applies a small drop of blood (usually 3–5 μL) to a testing strip, from which a portable glucose meter can determine the glucose concentration of the blood by enzymatic means within 5 to 30 seconds. In this way, patients can immediately determine their capillary blood glucose concentration at any time.

Patients with type 1 diabetes should monitor blood glucose frequently. In the DCCT, insulin doses for patients in the intensive treatment arm were adjusted according to the results of SMBG performed at least four times a day.[24] In other studies there was a linear relationship between A_{1c} and frequency of SMBG up to 10 measurements per day.[25]

Given the value of blood glucose data, it is important to consider potential problems that are inherent in the process of self-monitoring. The patient's use of the meter and self-monitoring technique should be reviewed periodically in the clinic. There can be clinical variability in the accuracy of US Food and Drug Administration (FDA)-approved meters,[26,27] so patients need to use well-validated devices with unexpired test strips that are kept in the provided sealed bottle or foil wrapper. Glucose monitors utilize an enzymatic reaction linked to an electrochemical reaction, either glucose oxidase or glucose dehydrogenase,[28] although most now use the latter method. Glucose oxidase monitors are sensitive to the oxygen available and should only be used with capillary blood in patients with normal oxygen saturation. Higher oxygen tensions (i.e., arterial blood or oxygen therapy) may result in false low glucose readings, and low oxygen tensions (i.e., high altitude, hypoxia, or venous blood readings) may lead to false high glucose readings. Glucose dehydrogenase monitors are not sensitive to oxygen.

Interference with SMBG results can occur from a variety of substances. For glucose oxidase monitors, this includes uric acid, galactose, xylose, acetaminophen, L-dopa, and ascorbic acid. Glucose dehydrogenase monitors have had interference issues with icodextrin, which is used in peritoneal dialysis.[29]

Continuous Glucose Monitoring. Because blood glucose concentrations are dynamic and fluctuate constantly, it is readily apparent that the limited data provided by even frequent SMBG might not be truly representative of an individual's glucose excursions. In this context, CGM devices represent an important development. This technology utilizes the fact that glucose in interstitial fluid can reflect blood glucose levels.[30] CGM systems typically consist of a subcutaneous sensor that continuously measures the glucose concentration in interstitial fluid and sends a signal to a smart phone or a reader.[28] Using this input, the monitor determines a blood glucose concentration every 1 to 5 minutes that can be seen in real time by the patients and downloaded to a computer to provide a graphical retrospective display of the patient's glycemic profile over the period of time monitored.[31] There are two classes of CGM devices available: "professional" or blinded CGM, in which the devices are owned by the clinic and worn by the patient episodically, and "personal" CGM, which are devices owned by the patient and worn nearly continuously. Personal CGM devices are either real time (RT)-CGM, which provides patients with alarms and alerts on a continuous basis, or intermittently scanned (IS)-CGM, which requires that the sensor is scanned with the reader/smart phone in order to display the data. IS-CGM does have the capacity to provide an optional low and high alarm.

Randomized clinical trials have been primarily done with RT-CGM devices. Depending on the trial and primary endpoint, these studies have shown reductions in A_{1c} levels[32] and reduction in rates of hypoglycemia.[33,34] This is true for patients on insulin pumps[32] as well as on multiple daily injections (MDI) of insulin,[35,36] and has been shown in older patients as well as younger individuals.[37] IS-CGM results have been more mixed, with fewer clinical trials and reductions in A_{1c} and hypoglycemia in some, but not all, studies.[38,39] However, multiple observational studies have shown benefit, particularly if the device is used in conjunction with a structured education program and is scanned frequently.[40,41] These studies have not used the most recently available IS-CGM systems that have alarms for high and low blood glucose levels, a feature not found on the previously studied devices.

Overall, individuals with type 1 diabetes should have access to CGM devices. Some require calibration with SMBG, and others do not. They vary in terms of how long they last, and all can be uploaded to cloud based programs for analysis. Patient preference and coverage determinations often dictate which device is used. Based on the available literature, for individuals with type 1 diabetes and episodes of hypoglycemia, particularly with hypoglycemia unawareness, RT-CGM is preferred.

In addition, the technology exists wherein CGM systems have been combined with insulin pumps in order to optimize insulin delivery. These are called HCL systems. The sensor data is fed into an algorithm that controls the delivery of insulin by the pump. These systems have been shown to improve A_{1c} and TIR, with reductions in rates of hypoglycemia.[42]

Glucose levels, either with SMBG or CGM, should be assessed before administration of insulin prior to a meal and at bedtime. Patterns of nocturnal hypoglycemia resulting from excessive bedtime insulin can be detected by blood glucose measurement in the early hours of the morning or reviewing overnight CGM data. Similarly, postprandial values 2 hours after a meal can assess the adequacy of the preprandial insulin dose. Patients should look at their blood glucose level before and during driving a motor vehicle, as well as before, during, and after exercise.

Monitoring of glucose levels is valuable only to the extent that the information it provides is used to guide treatment, and should be coupled with diabetes education. Glucose data can be used in real time, to determine insulin doses as well as to assess for hypoglycemia. The data can also be evaluated retrospectively for assessment of patterns and adjustments in dosing and food intake.

KEY POINTS

- Acute monitoring of glucose levels by either capillary testing, or now CGM systems, is an essential element of self-management of type 1 diabetes.

Measurement of Chronic Glycemic Control. Glucose can attach to proteins in the blood through an irreversible, nonenzymatic process, resulting in the formation of glycated proteins.[43] Because this process is irreversible, glucose remains attached to the protein until the latter is metabolized. The degree of glycation is a function of integrated blood glucose concentration over time. Thus, measurement of glycated proteins provides a means of estimating chronic blood glucose concentration over a time period proportional to the half-life of the protein in question.

Erythrocytes are freely permeable to glucose. In the circulation, glucose attaches irreversibly to hemoglobin in red blood cells, leading to the formation of glycated hemoglobins called hemoglobin A_{1a}, A_{1b}, and A_{1c}. Measurement of hemoglobin A_{1c} (also known as *A_{1c}, glycohemoglobin,* or *glycosylated hemoglobin*) has emerged as the most widely used test of chronic glycemic control. Specifically, the proportion of glycosylated hemoglobin to the total number of hemoglobin molecules reflects overall blood glucose concentration over the preceding 2 to 3 months.[44] Therefore, regular measurement of A_{1c} every 3 months is recommended as a method of determining overall glycemic control and evaluating the adequacy of the treatment regimen. For instance, a significantly elevated A_{1c} value, consistent with suboptimal glycemic control, would suggest the need for a change in the treatment regimen. Analysis of daily glycemic patterns from the patient's glucose records can indicate the specific changes to be made.

Many different types of assays can be used for measurement of glycated hemoglobins.[45] Some assays report A_{1c} as a percentage of total hemoglobin, while other methods measure total glycated hemoglobin. Thus, nonstandardization of assays can complicate comparison of A_{1c} measurements between laboratories. The National Glycohemoglobin Standardization Program, initiated in 1996, is an initiative that is designed to standardize laboratory A_{1c} assays to the DCCT reference method.[46] The International Federation of Clinical Chemistry developed reference methods for A_{1c} analysis, with A_{1c} reported in units of mmol/mol.[47]

The DCCT provided insight into the correlation between A_{1c} level and mean plasma glucose concentration.[48] This relationship has since been studied with the use of CGM data (Fig 39.6).[49]

In practice, in some situations the measured A_{1c} value may be discordant with the level that would be expected on the basis of the patient's SMBG or CGM results. This can be due to a number of factors. For instance, rapid red blood cell turnover leads to a disproportionate representation of younger erythrocytes, whose collective exposure to ambient blood glucose levels has been shorter than that of other red blood cells. Accordingly, A_{1c} levels tend to be reduced under such conditions.[50] Pregnancy and hemolytic anemias are examples of settings characterized by rapid red blood turnover, and hence lowered A_{1c} levels. Chronic kidney disease and anemia can cause alterations in

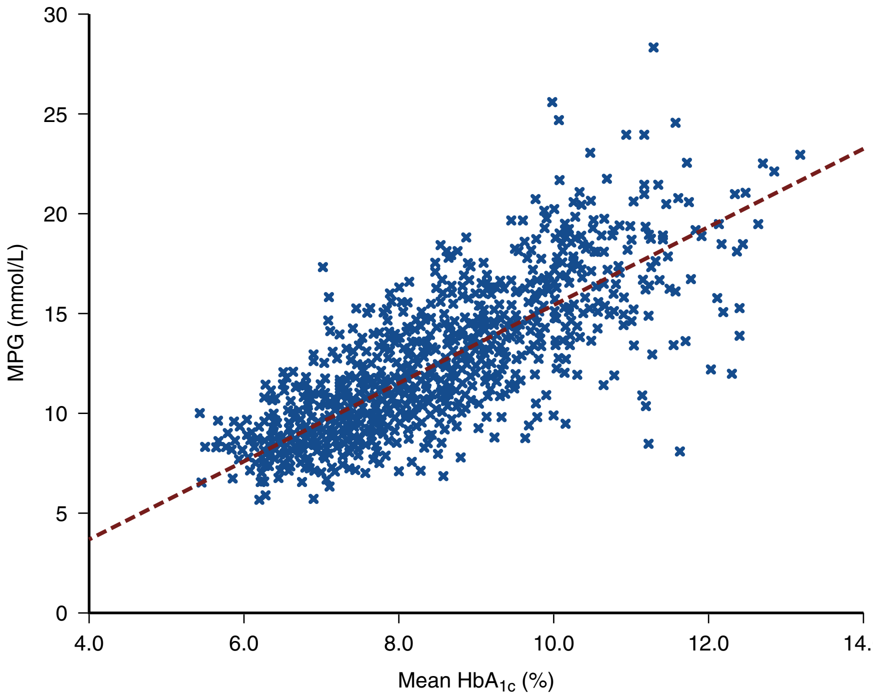

Fig. 39.6 The relationship between mean plasma glucose and mean glycosylated hemoglobin in the Diabetes Control and Complications Trial (n = 1429; r = 0.82). (From Rohlfing CL, Wiedmeyer HM, Little RR, et al. Defining the relationship between plasma glucose and HbA_{1c}: Analysis of glucose profiles and HbA_{1c} in the Diabetes Control and Complication Trial. *Diabetes Care.* 2002;25:276.)

red blood cell lifespan and impact A_{1c} levels.[51] Similarly, A_{1c} concentration may be lowered in hemoglobinopathies, such as thalassemia and sickle cell disease, because of a diminished propensity for glycation of the abnormal hemoglobin molecule. Conversely, depending on the assay used, A_{1c} values may be falsely elevated in the presence of hemoglobin F, the carbamylated hemoglobin formed in uremia, or acetaldehyde-bound hemoglobin (seen in alcohol abuse).[52] Finally, ethnicity can impact A_{1c} levels.[53]

In situations in which measurement of A_{1c} might be unreliable, an alternative approach to the estimation of glycemic control is the measurement of glycated serum proteins or albumin. The term *fructosamine* has been applied to the glycated proteins measured by such assays.[54] Given the 14- to 21-day half-life of albumin, a serum fructosamine measurement reflects mean blood glucose concentration over the preceding 1 to 2 weeks. Generally, serum fructosamine values correlate well with A_{1c} measurements.[55] However, certain caveats should be noted in measuring fructosamine. First of all, fructosamine values can be affected by conditions that alter the synthesis or clearance of serum proteins. Indeed, the question of whether or not to correct fructosamine assays for serum protein or albumin concentration remains controversial. Second, serum fructosamine levels show greater intrasubject variability than do A_{1c} measurements.[56] Third, unlike A_{1c}, fructosamine has not yet been shown to correlate with the risk for diabetic complications. Finally, use of CGM and calculation of the GMI can provide a reasonable estimation of overall glucose control over the past 2 to 4 weeks and may be more clinically relevant and accessible.

Ketone Testing

The presence of detectable levels of ketones in urine or blood may indicate impending or established ketoacidosis in patients with type 1 diabetes. Accordingly, patients should test for ketones in the following situations: 1) when blood glucose concentrations are persistently elevated, 2) during periods of acute illness or stress, or 3) when the patient is experiencing symptoms compatible with ketoacidosis, such as nausea, vomiting, and abdominal pain.[57] Traditionally, patients have used urine dipsticks to test for ketonuria. However, home monitors have been developed that can measure the capillary blood concentration of β-hydroxybutyrate, the most prevalent intermediate molecule in ketone formation.[58] Blood ketone testing avoids some of the limitations of traditional urinary ketone testing, such as false-positive readings, the inability to detect β-hydroxybutyrate (urinary dipsticks measure different ketone bodies), and patient reluctance to perform urinary testing. In studies to date, home capillary blood ketone measurement appears to be more sensitive than urinary testing in the detection of ketosis.[59,60] The use of blood ketone monitoring by patients is expected to increase in the future. In the clinical setting, serum ketone measurement is recommended over urinary testing.

Complication Surveillance

An essential component of ongoing care for patients with type 1 diabetes is surveillance for complications and comorbidities, as follows:

1. Retinopathy: Initial dilated and comprehensive eye examination should be performed at the time of diagnosis of type 1 diabetes and at regular intervals thereafter.[17] In patients without retinopathy who are well controlled, the interval may be every 2 years; for others receiving treatment, it could be monthly. Retinal photographs can suffice for screening if used appropriately.[61]
2. Nephropathy: Patients with type 1 diabetes should undergo an annual screening test for the presence of albuminuria.[17] The preferred screening test is a measurement of the albumin-to-creatinine ratio in a random, spot urine sample.[62] A serum creatinine and estimated glomerular filtration rate should also be obtained annually.
3. Neuropathy and foot care: A comprehensive foot examination should be performed annually.[17] This examination includes evaluation of sensation by 10-g Semmes–Weinstein monofilament, testing of vibration sense by tuning fork, assessment of superficial pain sensation, palpation, and visual inspection. In screening for neuropathy, superficial pain sensation testing, monofilament examination, and vibration testing all show similar operating characteristics and may be used interchangeably.[63] In patients with high-risk feet, an exam should be done at each visit, and patients should be encouraged to perform home foot exams daily.
4. Cardiovascular disease: Regular evaluation of cardiovascular risk factors is recommended. Blood pressure should be measured at every diabetic clinic appointment. Lipid profile should be tested annually. Screening exercise stress testing may be considered in patients with typical or atypical cardiac symptoms; abnormal resting electrocardiogram; a history of peripheral or cerebrovascular disease; or sedentary lifestyle, age over 35 years, and plans to start a vigorous exercise program. Weight should be measured at office visits, and weight loss discussed with patients who are obese or overweight.
5. Other: Other potential associated problems that warrant periodic screening include erectile dysfunction, depression, diabetes distress, celiac, and thyroid disease. Cognitive function screening may be needed in seniors.

KEY POINTS

- Measurement of hemoglobin A_{1c} for monitoring chronic glycemic control and surveillance for complications of diabetes are standard elements in the clinical management of type 1 diabetes.

INSULIN THERAPY

Principles of Insulin Replacement

Insulin replacement strategies in type 1 diabetes ideally aim to mimic the normal physiologic secretion of insulin by the pancreas.[6] Therefore, to appreciate the rationale underlying the design of current insulin replacement regimens, an understanding of the basic structure and biochemistry of endogenous insulin is necessary (Fig. 39.7). This topic, discussed in detail in Chapter 29, is reviewed briefly here.

The pancreatic β cells secrete endogenous insulin into the portal venous system in response to physiologic demand for glucose homeostasis, as determined by nutrient intake and energy expenditure. Despite broad fluctuations in these determinants, healthy individuals are able to maintain plasma glucose concentration within a narrow range of 3.5 to 7.0 mmol/L throughout the day (Fig. 39.8).[64] This normal glucose homeostasis requires tightly regulated insulin secretion that consists of two components: a basal secretion rate and surges of markedly increased secretion following ingestion of a mixed meal. Accounting for approximately 40% of total 24-hour pancreatic insulin output, the basal secretion of approximately 1 μ/hour serves to limit hepatic glucose production and adipocyte lipolysis in the postabsorptive (fasting) state, such as between meals and overnight.[65] Conversely, with ingestion of a mixed meal, dietary secretagogues (e.g., glucose, amino acids) and gastrointestinal hormones (e.g., glucagon-like peptide 1) stimulate robust pulses of insulin secretion up to five times the basal rate. These pulses regulate postprandial glycemia by inhibiting hepatic glucose production and increasing peripheral glucose uptake. Insulin secretion is also affected by energy expenditure. For instance, with moderate exercise, insulin secretion rapidly decreases to prevent hypoglycemia.[65] Conversely, with strenuous exercise, catecholamine-mediated hyperglycemia may occur, leading to increased insulin secretion in the postexercise period.[66] Thus, the tight coupling of insulin secretion to plasma glucose concentration in healthy individuals (see Fig. 39.8) requires the complex integration of multiple signals of nutrient availability and energy expenditure.

In providing insulin replacement for patients with type 1 diabetes, the task at hand is to recreate this complex physiology. Insulin replacement strategies in type 1 diabetes aim to faithfully imitate both basal secretion and the appropriately integrated prandial surges that are seen in nondiabetic individuals. Generally, one component of the treatment regimen serves as basal insulin (i.e., simulates basal insulin secretion by the pancreas between meals, overnight, and in the fasting state), while a second component is considered meal insulin (i.e., simulates the normal prandial insulin surge). In this context, important factors to consider in the design of the treatment regimen include the types of insulin to be used for basal and meal coverage and the method of delivery.

KEY POINTS

- The goal of insulin replacement therapy in type 1 diabetes is to imitate both basal secretion and the appropriately integrated prandial surges that characterize insulin secretion by the pancreas in individuals without diabetes.

Insulin Preparations

For the first 60 years after the introduction of insulin therapy in 1922, the only commercially available preparations were animal insulins derived from bovine or porcine pancreatic extracts. Porcine and bovine insulin preparations differ from human insulin by one and three amino acids, respectively. The use of animal insulins, however, was inherently complicated by several issues, including potential supply limitations, incomplete purification, and a propensity to induce the formation of antiinsulin antibodies (which may affect the activity and absorption of the exogenous animal insulin and lead to unpredictable pharmacodynamics, although this relationship is controversial). These issues were reconciled with the introduction of recombinant human insulin in the 1980s.[67] The past three decades have seen further advances, with the introduction of insulin analogs bearing molecular modifications that confer advantageous pharmacokinetics. Recombinant human insulin and the newer analogs are now the main preparations used in the treatment of type 1 diabetes.

In selecting types of insulin for use in a treatment regimen, the most important parameters to consider are the onset, peak, and duration of action of the given insulin preparation (Table 39.2). Commercially available human insulins and analogs include ultrarapid-, rapid-, short-, intermediate-, and long-acting preparations. The pharmacokinetic properties will determine whether a preparation should be used as either meal insulin or basal insulin. Specifically, ultrarapid-, rapid-, and short-acting preparations are used as meal (or bolus) insulins, and intermediate- and long-acting preparations provide basal insulins.

Human Insulins. Human insulin was the first medication to be commercially manufactured using recombinant DNA technology. Currently available human insulins include short-, intermediate-, and long-acting preparations. Each preparation has advantages and disadvantages, which will be considered in turn.

Short-Acting Human Insulin: Regular. Regular recombinant human insulin is identical to the endogenous insulin polypeptide. In solution, however, regular insulin tends to self-associate, first forming dimers and subsequently hexamers. After subcutaneous injection, the absorption of hexameric insulin molecules is delayed, pending dissociation into monomers and dimers, which can diffuse rapidly from subcutaneous tissue into the systemic circulation.[68] This slowed absorption has important pharmacokinetic implications, leading to 1) a modestly delayed onset of biologic action *in vivo* (30–60 minutes after injection), 2) a relatively late peak effect (2–4 hours after injection), and 3) a prolonged duration of action (6–8 hours) (see Table 39.2).[69] Clearly, this pharmacokinetic profile is quite different from the rapid and short-lived endogenous insulin response to a mixed meal that is seen in individuals without diabetes. Therefore, although regular insulin was widely used in the past, its role as meal insulin has declined since the introduction of rapid-acting analogs. However, in the United States, where the cost of insulin is a major issue, regular insulin may need to be used as the prandial insulin, because it is much less expensive than analog insulin.[70]

Intermediate-Acting Human Insulin: Neutral Protamine Hagedorn and Lente. The development of intermediate-acting

TABLE 39.2 **Approximate Pharmacokinetic Properties of Human Insulin and Insulin Analogs Following Subcutaneous Injection**

Insulin Preparation	Onset of Action	Peak of Action	Duration of Action
Meal Insulin			
Fast-acting aspart	~3–4 minutes	1 hour	3–5 hours
Ultrarapid lispro	~3–4 minutes	1 hour	3–5 hours
Lispro	10–15 minutes	1–1.5 hours	3–5 hours
Aspart	10–15 minutes	1–2 hours	3–5 hours
Glulisine	10–15 minutes	1–2 hours	3–5 hours
Regular	30–60 minutes	2–4 hours	6–8 hours
Basal Insulin			
Neutral protamine Hagedorn	2.5–3 hours	5–7 hours	13–16 hours
Lente	2.5–3 hours	7–12 hours	Up to 18 hours
Detemir	2–3 hours	6–8 hours	≈24 hours
Glargine U100	2–3 hours	No peak	≈24 hours
Glargine U300	6 hours	No peak	24–36 hours
Degludec	2–4 hours	No peak	>42 hours

human insulins reflected the need for an exogenous insulin preparation that could mimic the basal insulin secretion that is observed in individuals who do not have diabetes. The principle underlying the development of these insulins is that the rate of absorption of exogenous insulin from subcutaneous tissue can be significantly reduced by manipulating its suspension. First introduced in 1946, neutral protamine Hagedorn (NPH) insulin is a suspension of insulin complexed with protamine and zinc.[71] NPH is poorly absorbed from subcutaneous tissue, leading to delayed onset of action (2.5–3 hours), late peak effect (5–7 hours), and prolonged duration of action (13–16 hours) (see Table 39.2). A second intermediate-acting insulin preparation is lente, a crystalline suspension of insulin with zinc and acetate. It exhibits a pharmacokinetic profile similar to that of NPH, but with a slightly later peak and longer duration of action.

The intermediate-acting insulins show substantial variation in subcutaneous absorption, both within an individual patient and between patients, resulting in variable glycemic excursions.[72] Indeed, variability in the absorption of intermediate-acting insulin may account for as much as 80% of day-to-day variation in blood glucose concentrations.[73] Other factors that contribute to the unpredictability of NPH and lente are dose-dependent changes in pharmacokinetics and the practical variability associated with resuspension of these insulin preparations by the patient before subcutaneous injection.

Given their underlying pharmacokinetic profiles (duration of action of 13–18 hours) and clinical variability in action, the intermediate-acting insulins generally do not provide adequate basal insulin coverage. To increase their utility as basal insulins, these preparations are given twice daily in at least 20% of patients with type 1 diabetes.[74] Moreover, their peak effect is an undesirable quality in a basal insulin, insofar as it is clearly dissimilar to the relatively peakless profile of basal insulin secretion seen in an individual without diabetes.

Insulin Analogs. The pharmacokinetic shortcomings of human insulin preparations have provided a strong impetus for the development of insulin analogues. Through specific modifications of the insulin molecule (see Fig. 39.7), researchers have designed analogs with tailored pharmacokinetic profiles that allow for better meal or basal coverage. Currently available analogs include ultrarapid-, rapid-, and long-acting preparations.

Rapid-Acting Analogs: Lispro, Aspart, and Glulisine. Because the tendency to self-associate and the resultant delayed absorption of regular insulin compromise its effectiveness in mimicking the normal prandial insulin surge, it follows that an analog with enhanced absorption may provide a superior meal insulin. In this context, it was previously noted with interest that human insulin-like growth factor-1 (IGF-1), despite significant homology to insulin, exhibited a reduced tendency to form multimers. Identification of the salient structural differences between IGF-1 and insulin led to the development of lispro insulin, the first commercially available analog.[75] Lispro is identical to human insulin except for a reversal of the 28th and 29th amino acid residues (proline and lispro, respectively) of the normal insulin B chain (see Fig. 39.7). The resultant conformational change in the C-terminus of the B chain introduces steric hindrance at interfaces involved in dimerization. Thus, dimer formation with lispro is reduced by a factor of 300 compared with regular human insulin.[76] It is important to note that, apart from reduced self-aggregation, lispro displays biologic activity similar to that of regular insulin, with both comparable affinity for the insulin receptor and equivalent hypoglycemic potency.[75] Thus, clinically, lispro acts similarly to monomeric human insulin. It is rapidly absorbed in 10 to 15 minutes, reaches peak activity in 60 to 90 minutes, and has a duration of action of 3 to 5 hours (see Table 39.2).[77] With this pharmacokinetic profile, lispro mimics the normal prandial insulin surge in response to carbohydrate ingestion better than any of the exogenous meal insulins that preceded it do.

A second rapid-acting analog is insulin aspart, engineered through replacement of the proline residue at position 28 of the B chain with aspartic acid. The negative charge of the aspartic acid residue causes repulsion from other negatively charged amino acids and thus leads to decreased self-association of insulin aspart monomers.[78] Accordingly, insulin aspart has a similar pharmacokinetic profile to that of lispro and also is well suited for use as meal insulin.[79] Finally, a third, recently introduced, rapid-acting analog is insulin glulisine, in which the asparagine residue at position B3 of human insulin has been replaced by lysine and the lysine at position B29 has been replaced by glutamic acid.[80]

Given their pharmacokinetics, the rapid-acting insulin analogs have clear advantages over regular human insulin. Although patients must inject these analogs 15 or more minutes before meals, their use is associated with greater mealtime flexibility, easier application of carbohydrate estimation techniques (see the section entitled “Nutrition”), and improved quality of life.[81] Both lispro and aspart provide improved postprandial glycemic control with less postprandial and nocturnal hypoglycemia than occurs with regular insulin.[82-85] Despite these advantages, however, use of these rapid-acting analogs in intensive insulin regimens has not been uniformly associated with substantial improvement in A_{1c} compared with regular insulin.[81] Nevertheless, even in the absence of a consistent A_{1c} benefit, the combination of improved postprandial glycemia with less hypoglycemia suggests an overall reduction in glycemic excursion, and hence better glycemic control, with rapid-acting analogs.[83]

Ultrarapid-Acting Insulin. The requirement that first-generation rapid-acting analogs be administered 15 or more minutes before eating can be inconvenient for patients in practice. This limitation has led to the development of ultrarapid-acting insulin analogs that are absorbed even more rapidly than their predecessors. These formulations include fast-acting insulin aspart (Fiasp) and ultrarapid lispro.

Fiasp is a formulation of insulin aspart that contains the incipients nicotinamide and L-arginine, which contribute to faster initial absorption. Compared with aspart, Fiasp demonstrates a more physiologic profile, with faster onset and greater early glucose-lowering effect.[86,87] In clinical trial comparison of Fiasp versus aspart as part of basal-bolus therapy in type 1 diabetes, these properties have translated into better postprandial glycemic control with Fiasp.[88,89]

Ultrarapid lispro is a formulation of lispro in which the locally active excipients citrate and the prostacyclin analog treprostinil have been added to enhance insulin absorption. Specifically, treprostinil increases local vasodilation, while citrate enhances vascular permeability at the injection site.[90] Accordingly, ultrarapid lispro demonstrates faster onset of action and greater early glucose-lowering compared with lispro.[90] As observed with Fiasp, these features have yielded better postprandial glycemic control when comparing ultrarapid lispro to lispro in basal-bolus therapy for type 1 diabetes.[91]

Long-Acting Analogs: Glargine (U100), Glargine (U300), Detemir, Degludec (U100, U200). An ideal basal insulin would have a peakless, 24-hour time-action profile.[92] Attempts to develop long-acting analogs have focused on methods of achieving slow, prolonged absorption following subcutaneous injection. Insulin glargine (U100), the first commercially available long-acting analog, was introduced to the US market in 2001. It has two modifications compared with human insulin: two arginines have been added to the C-terminus of the B chain, and a glycine residue replaces an acid-sensitive asparagine at position A21.[93] These changes have shifted the isoelectric point of glargine toward neutrality, such that this analog is completely soluble in its acidic injection solution at pH 4.0 but is much less soluble at the neutral physiologic pH of subcutaneous tissue. After injection into subcutaneous tissue, the acidic injection solution is neutralized, causing glargine to microprecipitate.[93] Glargine subsequently is slowly absorbed into the systemic circulation from the subcutaneous microprecipitates, resulting in a smooth and gradual rise in serum concentration. Therefore, the pharmacokinetic profile of glargine shows an onset of action 2 to 3 hours after injection with a relatively peakless, 24-hour duration of action (see Table 39.2).[94] Moreover, glargine is associated with less variability in absorption than is either NPH or lente.[95,96] Furthermore, its *in vivo* hypoglycemic potency is equivalent to that of human insulin. The promise associated with these properties has been further supported by clinical trial evidence demonstrating lower fasting plasma glucose levels and less hypoglycemia (including nocturnal hypoglycemia) with the use of glargine, compared with NPH, as basal insulin in intensive therapy.[97-99]

Glargine U300 is a three times more concentrated formulation of glargine that provides a long-acting, less variable basal insulin. Owing to its greater concentration and smaller volume, the microprecipitates that form following the subcutaneous injection of glargine U300 take longer to be absorbed.[100] The resultant slower release of glargine U300 leads to a longer duration of action, a flatter 24-hour profile, and less variability compared with glargine U100.[101,102] In head-to-head comparison in type 1 diabetes, glargine U300 provided similar glycemic control, with possible reduction in the risk of nocturnal hypoglycemia.[103,104]

The design of insulin detemir, a second long-acting analog, reflects a different approach to achieve long-acting basal coverage. With detemir, the B30 amino acid has been removed, and a 14-carbon aliphatic fatty acid has been acylated to the B29 amino acid.[105] This modification allows for reversible binding between albumin and the added fatty acid. After injection, an equilibrium develops between free and bound detemir, in which 98% of the analog is bound to albumin. Because only the free analog binds to the insulin receptor, the duration of action of detemir is prolonged, owing to sustained release of the analog that has been bound to circulating albumin.[106] The time-action profile of insulin detemir is characterized by peak activity at 6 to 8 hours after injection and a prolonged 24-hour duration of action (see Table 39.2).[106] Clinically, significant reductions in hypoglycemic risk have been demonstrated with detemir as basal insulin in intensive regimens compared with NPH.[107] In addition, detemir has been associated with more predictable glycemic control than NPH, with significantly less within-subject variation in blood glucose levels.[108,109] However, it is not as long-acting as the other long-acting insulins, and twice-daily administration is often required in people with type 1 diabetes.

Insulin degludec, available in U100 and U200 formulations, is a new-generation ultralong-acting basal insulin designed to provide a smooth, peakless pharmacokinetic profile and a prolonged duration of action of more than 40 hours.[110,111] Its structure maintains the amino acid sequence of human insulin, but with the deletion of threonine in position B30 and the addition of a fatty acid side chain attached to lysine in position B29 of the insulin B chain through a glutamic acid linker. In solution, degludec exists in a dihexameric state. Following subcutaneous injection, additives in the formulation disperse (primarily phenol) and degludec dihexamers self-associate to form large multihexamers. The resultant depot provides a slow, continuous release of degludec monomers that are absorbed into the circulation, yielding an ultralong duration of action. In clinical studies, degludec has provided effective glucose lowering, with low rates of hypoglycemia, particularly overnight.[112-114] In patients with type 1 diabetes on intensive insulin regimens, degludec has shown similar glycemic control as glargine U100 but with reduced risk for nocturnal hypoglycemia.[113,114] Overall, it is similar to glargine U300 in clinical practice.

KEY POINTS

- The pharmacokinetic shortcomings of human insulin preparations have led to the development of basal and meal insulin analogs that have been designed to more closely replicate the features of physiologic insulin secretion.

Inhaled Insulin. Despite their improved performance, modern subcutaneous insulin preparations have not been able to replicate the rapid on/off features of endogenous insulin secretion. In this context, pulmonary delivery of inhaled insulin has been proposed as an option of interest. Technosphere insulin is a dry powder formulation of regular human insulin adsorbed onto microparticles containing the excipient fumaryl diketopiperazine, which is highly soluble in water and at basic pH.[115,116] When these inhaled microparticles reach the lungs, they dissolve in the setting of physiologic pH and release the insulin for systemic absorption. The rapid absorption of insulin is further facilitated by the enormous surface area of well-perfused lungs. Inhaled insulin can thus provide meal insulin coverage. In patients with type 1 diabetes receiving basal insulin therapy, technosphere insulin achieved noninferiority in A_{1c} reduction compared with insulin aspart, coupled with less hypoglycemia and less weight gain but also an increased incidence of cough.[116] Monitoring of pulmonary function is recommended in patients receiving inhaled insulin.

Intensive Insulin Therapy Regimens

The DCCT clearly established that the use of intensive insulin therapy can achieve lower A_{1c} concentrations and can reduce the risk for microvascular complications in patients with type 1 diabetes. Therefore, intensive insulin therapy currently is recommended for all patients with type 1 diabetes. Two main regimens can be utilized to provide intensive insulin therapy: MDI and CSII. Both regimens attempt to mimic physiologic insulin secretion through appropriate meal and basal insulin replacement. Ultimately, the choice of insulin regimen generally is determined by patient-driven factors, including lifestyle issues, finances, and personal preference. As noted above, glycemic control is improved in individuals using CGM in addition to either MDI or CSII therapy.

Multiple Daily Injection Regimen. An MDI regimen involves at least four injections of insulin per day, consisting of boluses of meal insulin before each meal and at least one injection of basal insulin, usually at bedtime. If needed, a second injection of basal insulin may be added at breakfast or before lunch. The meal insulin of choice is an ultrarapid- or rapid-acting analog. Use of rapid-acting analogs in MDI therapy has been associated with better postprandial glycemic control, a reduced incidence of hypoglycemia, and improvements in quality of life, compared with regular insulin.[69] On the other hand, although some studies have shown a significant decrease in A_{1c} with the use of rapid-acting analogs as compared with regular insulin in MDI therapy, other studies have not shown a significant difference in overall glycemic control.[69] As noted earlier, however, this phenomenon likely reflects suboptimal basal insulin replacement in the studies in question. Moreover, with similar A_{1c}, the combination of reduced postprandial glycemic excursion with less hypoglycemia suggests reduced overall glycemic variability (and hence better control) with the use of rapid-acting analogs compared with regular insulin in MDI therapy.

In the past, basal insulin replacement in MDI usually has consisted of bedtime injection of NPH, lente, or ultralente. In older clinical studies of MDI regimens using rapid-acting analogs as meal insulin, all three of these basal preparations have shown similar efficacy with regard to glycemic control and incidence of hypoglycemia. Given their pharmacokinetic advantages, however, the long-acting analogs have become the basal insulins of choice in MDI therapy. In studies comparing glargine and NPH as basal insulins in MDI regimens, glargine (U100 and U300) and degludec have been associated with improved fasting glucose levels and reduced rates of hypoglycemia. A metaanalysis has shown that, compared with NPH, long-acting basal insulin analogs (glargine and detemir) have a small but significant effect on A_{1c}, coupled with reduced risk for nocturnal and severe hypoglycemia in patients with type 1 diabetes.[117] In addition, a second, prebreakfast injection of basal insulin is far less likely to be required with glargine than with NPH, lente, or ultralente. Indeed, in studies using lispro as meal insulin in MDI regimens, glycemic control was similar with a single injection of glargine at breakfast, dinner, or bedtime.[118] Similarly, degludec can be given at any time of day.[119] Studies evaluating the efficacy of MDI regimens that use rapid-acting analogs for meal insulin and long-acting analogs for basal coverage have been performed,[120] proving that this combination will provide the most physiologic insulin replacement among MDI regimens.

Continuous Subcutaneous Insulin Infusion. The external insulin infusion pump was first developed in the late 1970s, providing the basis for modern CSII therapy.[121] With CSII, an external infusion pump delivers a continuous infusion of rapid-acting insulin through a catheter inserted into the subcutaneous tissue of the abdominal wall. The pump is preprogrammed by the patient to deliver insulin continuously at a specified rate that is designed to meet the individual's basal insulin demands. For meal coverage, patients use the pump to deliver a specified bolus of insulin before eating. The rapid-acting or ultrarapid-acting insulin analogs are the insulins of choice in CSII, as both lispro and aspart have been shown to reduce postprandial glycemia, A_{1c} concentration, and the incidence of hypoglycemia compared with regular insulin in this setting.[122-124]

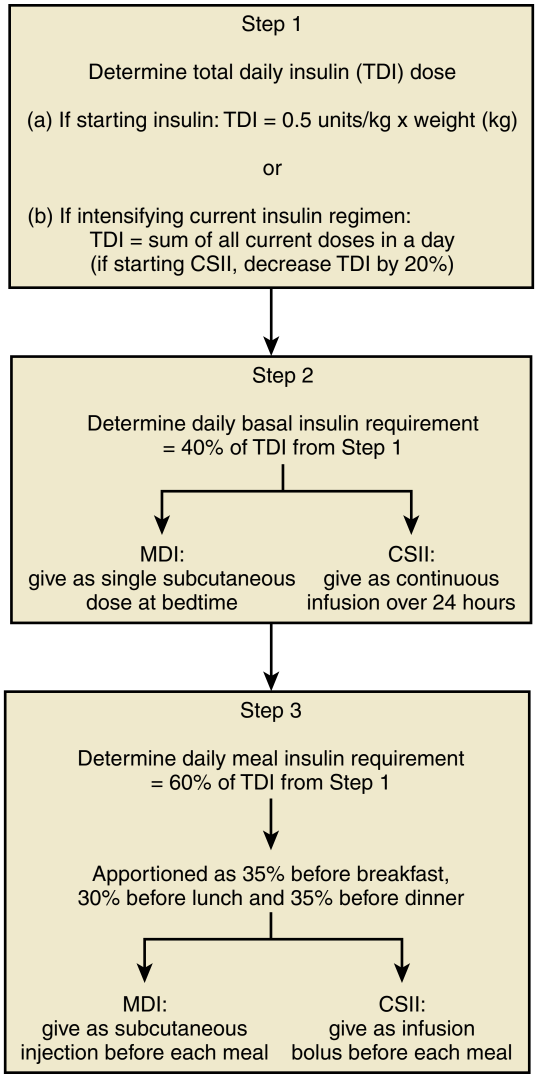
CSII offers advantages over MDI therapy in terms of convenience and flexibility.[125] Because the continuous infusion provides basal insulin at all times, the timing of meals with CSII, unlike with MDI, is completely flexible. At any given time, the rate of basal infusion can be adjusted immediately—an option that is not available with MDI. Moreover, current insulin pumps have multiphasic basal settings, allowing the user to set varying rates of basal insulin replacement at different times of the day depending on requirements. For instance, the pump can be preprogrammed to increase the basal rate of insulin infusion in the early morning hours in patients in whom the physiologic early morning secretion of growth hormone otherwise would lead to hyperglycemia (the "dawn phenomenon"). In addition, many insulin pumps have programming capabilities that facilitate dose selection for carbohydrate counting and insulin-correction boluses.

More recently, HCL technology has become available. These systems use a traditional insulin pump that is enabled to response to a control algorithm, which uses data from a CGM to adjust insulin delivery. These systems still require that the user enter his or her carbohydrates and give premeal insulin bolus doses, but they adjust the basal rates to avoid hypo- and hyperglycemia, and in some cases can provide "autocorrection" boluses.[126,127] Automating insulin delivery in this way reduces A_{1c} levels and rates of hypoglycemia and improves TIR.[126,127]

The major limitation with CSII is the significant cost associated with the pump and necessary supplies, such as the tubing, which must be changed every 48 to 72 hours. Another disadvantage is the risk for infection at the insertion site of the catheter. Catheter site infections occur at an estimated rate of 7.3 to 11.3 events per 100 years of patient follow-up.[128] These infections usually are readily treatable with antibiotics and a change of insertion site. In rare cases, a subcutaneous abscess requiring surgical drainage can develop. Finally, interruption of basal insulin delivery due to pump malfunction or catheter disruption can rapidly lead to hyperglycemia or even ketoacidosis, as patients will quickly become markedly insulinopenic owing to the use of only rapid- or short-acting insulin in CSII.[129]

Clinical Efficacy of Continuous Subcutaneous Insulin Infusion Versus Multiple Daily Injections. In clinical trials comparing optimized MDI therapy with CSII, glycemic control has been found to be similar with both regimens, especially when using insulin analogs.[125] Both are simply ways to give insulin and depend on user input and adjustments, especially for meals and corrections. However, both are improved by the addition of CGM, and combining CGM with an HCL system does provide additional benefit.[126,127]

Implementation of Intensive Insulin Therapy. Implementation of an intensive insulin regimen using MDI or CSII can be accomplished in many ways. In general, starting doses are estimated by using an algorithm such as the method shown in Fig. 39.9. The initial total daily insulin (TDI) requirement is estimated at 0.5 unit/kg of body weight, although most adult patients with type 1 diabetes ultimately require 0.6 to 0.7 unit/kg. Alternatively, for patients who are already on an insulin regimen, TDI is simply the sum of all current insulin doses. When CSII is implemented in such a patient, this TDI dose must be reduced by 20% to determine the total daily amount of insulin to be delivered by the pump.



Step 1
Determine total daily insulin (TDI) dose
(a) If starting insulin: TDI = 0.5 units/kg x weight (kg)
or
(b) If intensifying current insulin regimen:
TDI = sum of all current doses in a day
(if starting CSII, decrease TDI by 20%)
Step 2
Determine daily basal insulin requirement
= 40% of TDI from Step 1
MDI:
give as single subcutaneous
dose at bedtime
CSII:
give as continuous
infusion over 24 hours
Step 3
Determine daily meal insulin requirement
= 60% of TDI from Step 1
Apportioned as 35% before breakfast,
30% before lunch and 35% before dinner
MDI:
give as subcutaneous
injection before each meal
CSII:
give as infusion
bolus before each meal

Fig. 39.9 One algorithm for the determination of initial insulin doses when intensive insulin therapy using multiple daily injection or continuous subcutaneous insulin infusion is implemented. (Adapted from Shah BR, Zinman B. Insulin regimens for type 1 diabetes. In: Sperling MA, ed. *Contemporary endocrinology: type 1 diabetes: etiology and treatment.* Totowa: Humana Press; 2003:205.)

Basal insulin makes up approximately 40% to 50% of the total daily dose, depending on the carbohydrate consumption of the patient. With MDI, this basal insulin initially is provided with a single bedtime injection, although postabsorptive daytime hyperglycemia may subsequently dictate the need for a second dose of basal insulin before breakfast. With CSII, the total daily basal insulin is provided as a continuous infusion over 24 hours, with hourly basal rates typically ranging from 0.6 to 1.2 units/hour. The remaining 50% to 60% of the TDI is provided in the form of meal or bolus insulin, with lunch generally requiring less insulin than breakfast and dinner.

As an example, consider the following case of a patient who is currently on a nonintensified regimen of 12 units of NPH at both breakfast and bedtime and six units of regular insulin at breakfast and dinner. To convert this patient's insulin therapy to an intensified MDI regimen, the algorithm in Fig. 39.9 would be applied as follows:

- The TDI would be 12 + 12 + 6 + 6 = 36 units of insulin per day.
- The basal requirement would be estimated at 40% × 36 units = 14 units per day.
- The daily meal insulin requirement would be estimated at 60% × 36 units = 22 units per day. This meal insulin could be divided such that the patient receives 35% × 22 units = 8 units at breakfast, 30% × 22 units = 6 units at lunch, and 35% × 22 units = 8 units at dinner. These meal insulin doses ideally would be provided in the form of preprandial subcutaneous injections of a rapid-acting analog.

TABLE 39.3 Example of a Variable Insulin Dose Scale

Blood Glucose (BG), mg/dL	UNITS OF MEAL INSULIN Breakfast	Lunch	Dinner
<90	–2	–2	–2
Goal BG 90–130	x	y	z
131–180	+2	+2	+2
181–230	+4	+4	+4
231–280	+6	+6	+6
281–330	+8	+8	+8
>330	+10	+10	+10

Sample variable insulin dose scale to guide adjustment of meal insulin based on preprandial glucose levels. Baseline doses of x, y, and z units of meal insulin at breakfast, lunch, and dinner, respectively, are adjusted by the indicated amounts based on the preprandial glucose level. (Example for illustrative purposes only.)
(Adapted from Leadership Sinai Centre for Diabetes, Mount Sinai Hospital, Toronto, Ontario, Canada.)

In practice, the insulin doses calculated in Fig. 39.9 are adjusted continually by the patient on the basis of the following three considerations: 1) preprandial glucose concentration, 2) anticipated carbohydrate intake, and 3) upcoming physical activity. By determining the preprandial blood glucose level using capillary monitoring, the patient can adjust prandial insulin dosage using a variable insulin dose scale (Table 39.3). Using this approach, the patient is directed to take a higher dose of prandial bolus insulin when the blood glucose concentration is above a specified range. The second consideration in dose adjustment is anticipated carbohydrate intake. By estimating the amount of carbohydrate to be ingested in the upcoming meal (a practice that is referred to as *carbohydrate counting*), the patient can adjust the prandial insulin dose accordingly. Although most patients require an additional 1 unit of insulin per 10 to 15 grams of carbohydrate ingested at a meal, the actual ratio must be determined individually for each meal in any given patient. Finally, patients must consider the effects of upcoming physical activity when adjusting insulin dosage. For instance, with MDI therapy, prandial insulin administered at the meal before moderate exercise might have to be reduced, depending on the individual's glycemic response to exercise.[129,130] Patients using CSII have the additional flexibility of being able to adjust their basal insulin rate to accommodate for exercise and further reduce their insulin on board.

KEY POINTS

- The recommended treatment for type 1 diabetes is intensive insulin therapy, which can be delivered through either multiple daily insulin injections (MDI) or CSII with an insulin pump.

Complications of Insulin Therapy. Insulin therapy is lifesaving in patients with type 1 diabetes. Nevertheless, complications of insulin treatment can pose obstacles to the implementation of intensive therapy.

The most feared and serious complication of intensive insulin therapy is severe hypoglycemia (see Chapter 38). In the DCCT, the risk for hypoglycemia was approximately three fold higher in the intensive treatment group than in the conventional therapy arm.[131] Because insulin analogs were not available at the time of the DCCT, it is not clear whether this finding reflects current practice, although more recent data suggest that glycemia variability, rather than A_{1c} level, is the biggest risk for episodes of hypoglycemia. It is surprising that, despite the high rates of hypoglycemia with intensive therapy in the DCCT, no evidence of detectable long-term decline in cognitive function was noted in study participants after a mean 18 years of follow-up in the EDIC study.[132] Nevertheless, hypoglycemia is an important factor that may limit the ability to achieve optimal glycemic control. Hypoglycemia generally reflects an imbalance among carbohydrate intake, physical activity, and the dose of exogenous insulin. In addition, patients with type 1 diabetes have a deficient counterregulatory response to hypoglycemia.[133] Previous episodes of severe hypoglycemia and physiologic inability to detect the attendant symptoms (hypoglycemia unawareness) are other factors that are associated with increased hypoglycemic risk. Thus, a patient's propensity for hypoglycemia must be considered in establishing therapeutic goals, as excessive hypoglycemia is best managed by raising glycemic targets. Similarly, in patients with hypoglycemia unawareness, raising glycemic targets is utilized as a means of restoring physiologic awareness of hypoglycemic symptoms.[134] Specifically, with increased overall glycemia, the careful avoidance of further hypoglycemia can help to restore awareness and improve defective counterregulation.

Weight gain is another adverse effect that is associated with insulin therapy. In the DCCT, patients receiving intensive therapy gained 4.75 kg more than participants in the conventional treatment arm over the course of the study.[135] This effect reflects both insulin's anabolic properties and the decrease in glycosuria observed with improved glycemic control. Specifically, for patients with poor glycemic control, the elimination of glycosuria with insulin therapy will lead to a positive caloric balance and weight gain. In addition, intermittent hypoglycemia associated with intensive insulin therapy can lead to hunger and increased caloric intake. Concerns regarding weight gain may cause some patients to be reluctant to initiate intensive therapy and should be addressed by the healthcare team.

Rapid improvement in glycemic control following the initiation of intensive insulin therapy can cause transient exacerbation of underlying retinopathy.[137] Patients with proliferative retinopathy and baseline A_{1c} greater than 10% are at highest risk for this complication.[137] Baseline ophthalmologic evaluation with frequent surveillance should be considered for such patients when intensive therapy is started.[136] In addition, more gradual reduction in A_{1c} may be prudent in such cases.

Allergic reactions to insulin are rare, particularly because human insulin is much less immunogenic than were earlier animal insulins. Most allergic reactions to insulin reflect local hypersensitivity at the site of injection. Generalized allergic reactions can occur rarely. Protocols for desensitization have been developed for both local and systemic hypersensitivity to insulin.[138]

Lipohypertrophy refers to localized swelling at a site of repeated insulin injection. This complication is related to the lipogenic effects of insulin. Continued injection of insulin into sites of lipohypertrophy is discouraged, as absorption of the insulin can be erratic, which may lead to unpredictable glycemic effects. Lipoatrophy reflects a different pathophysiology, in which an immune-mediated response to exogenous insulin leads to atrophy of subcutaneous tissue at the site of injection.[139] With the current use of recombinant human insulin preparations and analogues, the problem of insulin-induced lipoatrophy is infrequent.

Adjustment of Insulin Therapy in Special Situations

The absence of endogenous insulin secretion in patients with type 1 diabetes dictates an absolute reliance at all times on exogenous insulin for both prandial and basal metabolic needs. Thus, even when not eating, patients with type 1 diabetes continue to require insulin therapy to meet basal requirements and to avoid diabetic ketoacidosis. Recognition of this principle underlies the appropriate management of their insulin therapy in special situations such as at times of intercurrent illness and during surgery.

Intercurrent Illness. The physiologic stress associated with illness stimulates the release of counterregulatory hormones that antagonize insulin action. Thus, during times of illness, patients are at risk for both hyperglycemia and diabetic ketoacidosis. During such times, regular monitoring of blood glucose concentrations at least every 4 hours is recommended. If hyperglycemia is detected, then supplemental insulin is indicated. Conversely, if blood glucose levels are low, then the amount of insulin taken at that time should be reduced significantly. As noted earlier, patients must not withhold insulin therapy completely. Instead, under such circumstances, patients are advised to drink sugar-rich fluids such as fruit juices to maintain adequate carbohydrate and fluid intake. If patients are unable to tolerate even this limited intake, however, then presentation to the hospital is necessary for administration of intravenous fluids.

Even with continued insulin therapy, patients with type 1 diabetes are at risk for developing ketoacidosis during times of illness owing to the effects of counterregulatory hormones in antagonizing insulin action and promoting ketogenesis. Frequent testing of blood ketone levels using a home capillary blood ketone monitor is recommended at such times. Alternatively, if such testing is unavailable at home, then traditional urinary ketone monitoring should be performed (see the section entitled "Ketone Testing" earlier in the chapter).

Surgery. The goals of perioperative management of patients with type 1 diabetes are avoidance of marked hyperglycemia and avoidance of hypoglycemia. As with periods of illness, surgery is associated with both physiologic stress that promotes hyperglycemia and reduced caloric intake that may predispose to hypoglycemia (because most surgical procedures are performed on fasting patients). As before, the principles of management include the need for continued insulin therapy and close metabolic monitoring. Typically, major surgical procedures are managed with intravenous insulin therapy and frequent blood glucose monitoring.

NUTRITION

The nutritional recommendations associated with healthy eating habits for the general public are also applicable to patients with type 1 diabetes.[17] The important difference in patients with type 1 diabetes is that dietary intake must be coordinated appropriately with insulin therapy and physical activity to achieve regulation of blood glucose levels. In particular, attention must be paid to the sources and amount of carbohydrate in the diet. Carbohydrate is the main dietary constituent that affects postprandial glycemic excursion, and hence prandial insulin requirements.[140] This concept has led to the practice of "carbohydrate counting."

Carbohydrate counting is a meal-planning approach in which patients are taught to estimate the carbohydrate content of a meal preprandially and to adjust their dose of meal insulin accordingly.[141] Most patients require 1 extra unit of insulin for each 10 to 15 g of carbohydrate ingested, although this ratio must be determined individually on the basis of personal food preferences and individual physiologic response. As such, carbohydrate counting is an integral component of patient education, and it is a skill that patients generally develop with the assistance of a clinical dietitian. Although the concept of carbohydrate counting was described shortly after the discovery of insulin,[142] its recent resurgence is linked in part to its inclusion as one of the dietary interventions in the intensive treatment arm of the DCCT. In the DCCT, the practice of adjusting food and/or insulin dosage in response to hyperglycemia emerged as a dietary behavior associated with improved glycemic control.[143] Moreover, carbohydrate counting allows for significant flexibility in food choices. Alternatively, for patients on fixed insulin doses who are unwilling to adjust prandial insulin dosage on the basis of dietary content, consistency of carbohydrate intake is advised.

Although carbohydrate content is the key modifier of prandial insulin dosage, total energy intake from protein and fat cannot be neglected. Total energy intake must be regulated to avoid unnecessary weight gain, particularly because intensive insulin therapy is frequently associated with weight gain as well.

Another important consideration that affects food choices is hypoglycemia. For instance, patients must recognize that ingested alcohol may reduce hepatic glucose production and mask the symptoms of hypoglycemia. Indeed, moderate alcohol consumption (one to two standard drinks) 2 to 3 hours after the evening meal can lead to delayed hypoglycemia the next morning after breakfast.[144] Conversely, patients are advised to avoid the overtreatment of hypoglycemia by excessive food intake, as this practice may lead to weight gain and significant glycemic excursion.

OTHER THERAPIES FOR TYPE 1 DIABETES

Islet cell and pancreas transplantation are therapies, in certain cases, for type 1 diabetes. These treatment modalities are discussed in detail in Chapter 41. However, due to multiple constraints, these are rarely done in otherwise healthy individuals with type 1 diabetes.

Premeal subcutaneous injection of pramlintide, an analogue of the pancreatic β cell hormone amylin that is otherwise deficient in patients with type 1 diabetes, is an FDA-approved therapy for adjunctive treatment of type 1 diabetes. Amylin affects glucose homeostasis through multiple mechanisms, including slowing of gastric emptying, regulation of postprandial glucagon, and reduction in food intake.[145] Pramlintide can be used in the treatment of type 1 diabetes in conjunction with insulin therapy (although it should be noted that pramlintide and insulin cannot be mixed in the same syringe). Overall, its effect on glycemic control is modest, but pramlintide may help to limit weight gain and reduce meal insulin requirements.[146]

Metformin, DPP-IV Inhibitors, and GLP-1 RAs

Off-label use of medications approved for individuals with type 2 diabetes has shown varying results.[147,148] Metformin is commonly added in individuals with type 1 diabetes and metabolic syndrome and/or polycystic ovarian syndrome (PCOS). Although studies have not shown improvements in A_{1c},[149,150] there may be a slight reduction in CVD risk,[150,151] as well as improvement in PCOS.[152]

DPP-IV inhibitors have shown no benefit, but use of GLP-1 RAs has been associated with weight loss[153,154] and, in some studies, improvements in glycemic control. The weight loss is not surprising, given that these agents are increasingly being used as weight loss medications in people without diabetes. SGLT-2 inhibitors, which act independently of β cell function, have been shown to provide some benefit in people with type I diabetes.[155-158] However, they are associated with an increased risk for diabetic ketoacidosis, including euglycemic diabetic ketoacidosis.[159] that limits their use. They are approved in Europe for individuals with type 1 diabetes and a body mass index greater than or equal to 27[160] who can follow guidelines for ketone testing.

FUTURE PERSPECTIVES

Despite remarkable advances in the more than 90 years since the discovery of insulin, the goal of sustained euglycemia in patients with type 1 diabetes remains largely unrealized. Even with the best treatments available, many patients continue to have A_{1c} levels that are above target[161]. When treating patients, consideration needs to be given to their psychosocial needs as well as to social determinants of health. Many underserved patients fail to realize the benefits seen by their more affluent counterparts.[162] Nevertheless, many different approaches to dealing with type 1 diabetes are being explored, from early detection and prevention to β cell replacement techniques and, perhaps most robustly, to ever newer and better diabetes technologies. Although diabetes is not curable, our treatment options continue to grow and must be adopted by as many as possible in order for people with type 1 diabetes to safely achieve and maintain their glycemic targets.

INTRODUCTION

Currently more than 1 in 10 Americans have diabetes, yet worldwide we can expect a 51% increase by 2045.[1,2] Fortunately, over the past three decades we have gained a better understanding of both islet function and insulin resistance, due to intense research of both nutrition and the impact of physical activity on metabolism. The introduction of a spectrum of new drugs with novel mechanisms of action provided clinicians with new tools. Later came large, randomized controlled trials showing that these agents could improve not only glycemia, but also cardiovascular and renal outcomes. Landmark studies have shown reductions in cardiovascular mortality, heart failure admissions, and need for renal replacement therapy with drugs originally developed to induce a modest reduction in HbA1c. This explosion of clinical trial data, especially in the past 5 years, has been extraordinary. Adding to this the increased use of diabetes-specific technology, treatment of type 2 diabetes is vastly different now than it was a few years ago. Nevertheless, the emphasis on nutrition and physical activity has not changed.

While this chapter is glucocentric in nature, control of blood pressure and hypercholesterolemia are both critical to the overall management of type 2 diabetes. There have also been many advances in the treatment of obesity that have powerful beneficial effects on diabetes outcomes.

The bulk of this chapter will deal with the glycemic approaches that will inform clinical decision-making. A comprehensive review of all the subtleties of diabetes management is beyond the scope of any chapter. An excellent source of information on these issues, which is updated annually, is the Clinical Practice Recommendations from the American Diabetes Association (ADA), which are published every January in Diabetes Care.

DIABETES EDUCATION

Diabetes is a complex condition that requires individuals with diabetes to make decisions about their self-care on a daily basis. Medical nutrition therapy (MNT) and diabetes self-management education and support (DSME/S) provided by qualified healthcare professionals using evidence-based approaches can result in improved clinical, psychological, and behavioral outcomes.[3,4] DSME/S is important for all people with diabetes and necessary to improve outcomes in a disease that is largely self-managed. DSME/S includes the ongoing process that facilitates the knowledge, skills, and abilities necessary for diabetes self-care throughout the life span. The support component includes activities outside of formal training that help individuals implement and sustain the behaviors needed to cope with and manage diabetes.[5] The National Standards for DSME/S are designed to define quality DSME/S and assist those who provide DSME/S services to implement evidence-based DSME/S.[6] The core curriculum topics of DSME/S,[6] also commonly known as the AADE-7 Self-Care Behaviors,[7] demonstrate successful outcomes and must be reviewed to determine which are applicable to the participant, and include the following: diabetes pathophysiology and treatment options; healthy eating; physical activity; medication usage; monitoring and using patient-generated health data; preventing, detecting, and treating acute and chronic complications; healthy coping with psychosocial issues and concerns and problem-solving.

Diabetes Self-Management Education and Support—the Evidence

Numerous studies have shown the benefits of DSME/S, which include improved clinical outcomes and quality of life while reducing hospitalizations and health care costs.[3,8,9] Key takeaways of DSME/S include:

- Average HbA1c reductions of 0.45% to 0.57% compared with usual care for people with a variety of modalities (lifestyle alone, oral and injected antihyperglycemic medication)[4,10]
- Reduction in the onset and/or worsening of diabetes-related complications[11,12]
- Participation in DSME/S reveals enhancement of empowerment and self-efficacy[13]
- Better health outcomes are associated with an increased amount of time spent with a diabetes educator[4,8,14]

Individualization of the Diabetes Education Care Plan

In 2020, a consensus report was authored by a diverse group of healthcare professionals from the ADA, the Association of Diabetes Care and Education Specialists, the Academy of Nutrition and Dietetics, the American Academy of Physician Assistants, the American Association of Nurse Practitioners, the American Academy of Family Physicians, and the American Pharmacists Association on DSME/S in adults with type 2 diabetes. The consensus report provides specific recommendations for both clinicians and the health system to increase access to and participation in DSME/S services.[3] The joint effort also provides details on the four key times to implement referrals to DSME/S: 1) at time of diagnosis, 2) on an annual basis, 3) when new complicating factors influence self-management, and 4) at times of transitions in care. The joint statement includes a DSME/S *Algorithm of Care* for healthcare professionals and integrates with MNT delivered by a registered dietician nutritionist (RDN), as well as emotional health provider by a mental health professional, if needed. Another helpful resource included in the consensus report is a checklist that identifies the areas of focus and action steps that can be considered (Table 40.1).

KEY POINTS

- Successful diabetes self-management education and support is evidenced-based, will lower HbA1c levels, and needs to be individualized.

NUTRITION

In addition to DSME/S, MNT provided by an RDN is an essential component of the diabetes treatment plan. The Institute of Medicine broadly defines nutrition therapy as the treatment of a disease or condition through the modification of nutrient or whole-food intake.[15] MNT is an evidence-based application of the Nutrition Care Process provided by the RDN and is the legal definition of nutrition counseling in the United States.[16] Individualized MNT is recommended by the National Academy of Medicine, provided by a RDN upon physician referral.[15] In the 2020 consensus report on the topic of DSME/S, the authors recommended that, in addition to DSME/S, adults with type 2 diabetes should also receive individualized or group diabetes MNT at diagnosis and as needed throughout the lifespan and during times of changing health status to achieve treatment goals.[3] Whenever possible, the unique academic preparation, skills, expertise, and training make the RDN the preferred member of the healthcare team to provide diabetes nutrition therapy. While advanced certification (such as Certified Diabetes Care and Education Specialist, formerly known as Certified Diabetes Educator) is not required, ideally the RDN will have comprehensive experience in and knowledge of diabetes care.[17]

Nutrition Therapy—the Evidence

Clinical trials and outcome studies of diabetes MNT provided by an RDN can improve HbA1c, with absolute reductions of up to 2% in type 2 diabetes at 3 to 6 months, depending on the duration of diabetes and level of glycemia.[17,18] Studies have demonstrated that ongoing RDN-provided follow-up encounters ranging from three to six sessions, with a minimum of one follow-up session annually, can be helpful in maintaining glycemic improvements. During this time, it can be determined whether target goals can be achieved by implementation of MNT in combination with physical activity or whether medication(s) will need to be combined with MNT. In addition, MNT helps prevent, delay, or treat other comorbidities commonly found with diabetes.[12,18] Not all studies of cardiovascular disease (CVD) risk factors report benefits, but in some cases this is likely due to a limited opportunity to show benefit, when, for example, lipid and blood pressure levels were already controlled or only mildly abnormal, or lipid-lowering or antihypertensive medications are present as cointerventions and mask the effect. MNT provided by an RDN is also cost-effective, and people who have received MNT show improved quality of life and clinical outcomes.[17]

The 2019 ADA Nutrition Therapy for Adults with Diabetes and Prediabetes: A Consensus Report reviewed research studies of persons with diabetes following different types of eating patterns, including Mediterranean-style, vegetarian and vegan, low-fat, low-carbohydrate (26%–45% total kcal) and very low carbohydrate (<26% total kcal/ketogenic diet), Dietary Approaches to Stop Hypertension) Paleo, and intermittent fasting.[19] The ADA nutrition consensus report concluded that a variety of eating patterns are acceptable for the management of diabetes. It should be noted that an eating pattern represents the totality of all foods and beverages consumed, whereas an eating plan (or diet) is a guide to help individuals plan what, how much, and when to eat on a daily basis of the foods emphasized in the individual's selected eating pattern.[20] Personal preferences (e.g., tradition, culture, religion, health beliefs and goals, economics) and metabolic goals should be considered when implementing one eating pattern over another. The eating pattern that the individual with type 2 diabetes chooses to follow will likely be the one that they will be able to follow long-term. Refer to Table 40.2 for the eating patterns reviewed for ADA nutrition consensus report, including a description of each eating pattern and list of potential benefits.

The ADA nutrition consensus report also includes recommendations for adults with type 2 diabetes who are overweight or obese. The authors recommend that it is important to encourage reduced energy intake as part of an individualized diabetes eating plan, along with enhanced physical activity.[19] In people with type 2 diabetes, a 5% weight loss is recommended to achieve clinical benefit, and the benefits are progressive. The report also recommends that the goal for optimal outcomes is 15% or more when needed and can be feasibly and safely accomplished. A recent systematic review of the effectiveness of diabetes MNT revealed mixed weight loss outcomes in participants with type 2 diabetes.[17] In addition to an eating plan that results in energy deficit, behavioral strategies and regular physical activity are critical components of any long-term weight loss and maintenance plan.[21,22] Weight loss interventions can be provided in usual care settings and telehealth programs.[19]

TABLE 40.1 Checklist for Providing and Modifying Diabetes Self-Management Education and Support at Four Critical Times

Four Critical Times	Primary Care Provider/ Endocrinologist/Clinical Care Team's Role in Diabetes Education	Diabetes Care and Education Specialist's Role in Diabetes Education
At diagnosis (series of visits)	• Answer questions and provide emotional support regarding diagnosis	• Assess cultural influences, social determinants of health, health beliefs, current knowledge, physical limitations, family support, financial and work status, medical history, learning preferences and barriers, literacy, and numeracy to determine which content to provide and how
	• Shared decision-making of treatment and treatment targets	• Medication—choices, access, action, titration, side effects
	• Teach survival skills to address immediate requirements (safe use of medication, hypoglycemia treatment if needed, introduction of eating guidelines)	• Monitoring blood glucose—when to check, interpreting and using glucose pattern management for feedback
	• Identify and discuss resources for education and ongoing support	• Physical activity—safety, short-term vs. long-term goals/recommendations
	• Make referrals for DSME/S and MNT	• Preventing, detecting, and treating acute and chronic complications
		• Nutrition—food plan, planning meals, purchasing food, preparing meals, portioning food
		• Risk reduction—smoking cessation, foot care, cardiac risk
		• Developing personal strategies to address psychosocial issues and concerns; adjusting to a life with diabetes
		• Developing personal strategies to promote health and behavior change
		• Problem identification and solutions
		• Identifying and accessing resources
Annually and/or when not meeting treatment targets	• Refer for new techniques, technology, and updated information	• Review and reinforce treatment goals and self-management needs
	• Assess and refer if self-management targets not met to address barriers to self-care	• Review barriers to treatment effectiveness
		• Emphasize reducing risk for complications and promoting quality of life
		• Discuss how to adjust diabetes treatment and self-management to life situations and competing demands
		• Support efforts to sustain initial behavior changes and cope with the ongoing burden of diabetes
When complicating factors develop	• Identify presence of factors that inhibit or facilitate achievement of treatment targets and personal goals	• Provide support for the provision of self-management skills in an effort to delay progression of the disease and prevent new complications
	• Discuss impact of complications and successes with treatment and self-management	• Provide/refer for emotional support for diabetes-related distress and depression
		• Develop and support personal strategies for behavior change and healthy coping
		• Develop personal strategies to accommodate sensory or physical limitation(s), adapt to new self-management demands, and promote health and behavior change
When transitions in life and care occur	• Develop diabetes transition plan	• Adjust diabetes self-management plan as needed
	• Communicate transition plan to new health care team members	• Provide support for independent self-management skills and self-efficacy
	• Establish DSME/S regular follow-up care	• Identify level of significant other involvement and facilitate education and support
		• Assist with facing challenges affecting usual level of activity, ability to function, health benefits, and feelings of well-being
		• Maximize quality of life and emotional support for the person with diabetes (and family members)
		• Provide education for others now involved in care
		• Establish communication and follow-up plans with the provider, family, and others
		• Develop goals and personal strategies to promote health and behavioral change and improve quality of life

Powers, et. al., Diabetes Self-management Education and Support in Adults With Type 2 Diabetes: A Consensus Report of the American Diabetes Association, the Association of Diabetes Care & Education Specialists, the Academy of Nutrition and Dietetics, the American Academy of Family Physicians, the American Academy of PAs, the American Association of Nurse Practitioners, and the American Pharmacists Association. *Diabetes Care*. 2020;43(7):1636–1649. https://doi.org/10.2337/dci20-0023.

TABLE 40.2 **Eating Patterns Reviewed for this Report**

Type of Eating Pattern	Description	Potential Benefits Reported
USDA Dietary Guidelines For Americans (DGA)	Emphasizes a variety of vegetables from all of the subgroups; fruits, especially whole fruits; grains, at least half of which are whole intact grains; lower-fat dairy; a variety of protein foods; and oils. This eating pattern limits saturated fats and *trans* fats, added sugars, and sodium.	DGA added to the table for reference; not reviewed as part of this Consensus Report
Mediterranean-style	Emphasizes plant-based food (vegetables, beans, nuts and seeds, fruits, and whole intact grains); fish and other seafood; olive oil as the principal source of dietary fat; dairy products (mainly yogurt and cheese) in low to moderate amounts; typically fewer than four eggs/week; red meat in low frequency and amounts; wine in low to moderate amounts; and concentrated sugars or honey rarely.	• Reduced risk of diabetes • HbA1c reduction • Lowered triglycerides • Reduced risk of major cardiovascular events
Vegetarian or vegan	The two most common approaches found in the literature emphasize plant-based vegetarian eating devoid of all flesh foods but including egg (ovo) and/or dairy (lacto) products, or vegan eating devoid of all flesh foods and animal-derived products.	• Reduced risk of diabetes • HbA1c reduction • Weight loss • Lowered LDL-C and non–HDL-C
Low-fat	Emphasizes vegetables, fruits, starches (e.g., breads/crackers, pasta, whole intact grains, starchy vegetables), lean protein sources (including beans), and low-fat dairy products. In this review, defined as total fat intake ≤30% of total calories and saturated fat intake ≤10%.	• Reduced risk of diabetes • Weight loss
Very low-fat	Emphasizes fiber-rich vegetables, beans, fruits, whole intact grains, nonfat dairy, fish, and egg whites and comprises 70%–77% carbohydrate (including 30–60 g fiber), 10% fat, 13%–20% protein.	• Weight loss • Lowered blood pressure
Low-carbohydrate	Emphasizes vegetables low in carbohydrate (such as salad greens, broccoli, cauliflower, cucumber, cabbage, and others); fat from animal foods, oils, butter, and avocado; and protein in the form of meat, poultry, fish, shellfish, eggs, cheese, nuts, and seeds. Some plans include fruit (e.g., berries) and a greater array of nonstarchy vegetables. Avoids starchy and sugary foods such as pasta, rice, potatoes, bread, and sweets. There is no consistent definition of "low" carbohydrate. In this review, a low-carbohydrate eating pattern is defined as reducing carbohydrates to 26%–45% of total calories.	• HbA1c reduction • Weight loss • Lowered blood pressure • Increased HDL-C and lowered triglycerides
Very low-carbohydrate (VLC)	Similar to low-carbohydrate pattern but further limits carbohydrate-containing foods, and meals typically derive more than half of calories from fat. Often has a goal of 20–50 g of nonfiber carbohydrate per day to induce nutritional ketosis. In this review a VLC eating pattern is defined as reducing carbohydrate to <26% of total calories.	• HbA1c reduction • Weight loss • Lowered blood pressure • Increased HDL-C and lowered triglycerides
Dietary Approaches to Stop Hypertension	Emphasizes vegetables, fruits, and low-fat dairy products; includes whole intact grains, poultry, fish, and nuts; reduced in saturated fat, red meat, sweets, and sugar-containing beverages. May also be reduced in sodium.	• Reduced risk of diabetes • Weight loss • Lowered blood pressure
Paleo	Emphasizes foods theoretically eaten regularly during early human evolution, such as lean meat, fish, shellfish, vegetables, eggs, nuts, and berries. Avoids grains, dairy, salt, refined fats, and sugar.	• Mixed results • Inconclusive evidence

From Evert, et al. Eating patterns reviewed for ADA Nutrition Consensus Report

Although numerous factors influence glycemic response to foods, monitoring intake of carbohydrates has demonstrated the most evidence for improving glycemia and may be applied in a variety of eating patterns that meet individual needs and preferences.[19] Evidence exists that both the quantity and type of carbohydrate eaten influence blood glucose levels; however, the total amount of carbohydrate eaten is the primary predictor of glycemic response.

For select adults with type 2 diabetes not meeting glycemic targets, or where reducing glucose-lowering medications is a priority, reducing overall carbohydrate intake with low- or very low-carbohydrate eating plans is a viable approach.[19] Day-to-day consistency in the amount of carbohydrate eaten at meals and snacks is reported to improve glycemic control, especially in persons on either MNT alone, glucose-lowering medications, or fixed insulin regimens.

Individualization of the Nutrition Prescription

The first step in developing a meal plan for the person with diabetes is to base it on an individualized assessment.[19] The initial visit with a RDN takes approximately 1 hour. The RDN focuses on the preferences and needs of the individual with diabetes to collaboratively develop a diabetes eating plan that can be followed long-term.[17,23] The RDN will take a detailed history, including an analysis of usual eating habits, past diets, comorbidities that affect nutrition, socioeconomic factors, cultural influences, and readiness to change in order to, collaboratively with the patient, identify the best approach to meal planning. This patient-centered approach sets the stage for the adoption of small, incremental lifestyle changes that include modifications in food and beverage choices as well as physical activity to improve overall health, reduce the risk of diabetes complications, and manage complications if indicated.[23]

Common meal planning approaches from the simple to complex include some of the following: reducing portion sizes, using the plate method, carbohydrate or calorie counting, using meal replacements, as well as incorporating behavioral strategies such as mindful eating, all while working within the eating preferences described by the person with diabetes.

Research studies and practice papers report the role of the RDN in organization-approved medication adjustment protocols.[24,25] The experienced RDN who has demonstrated competency in medication adjustment and practicing within their scopes of practice can help to reduce clinical inertia and/or reduce risk of hypoglycemia and hyperglycemia.

SUMMARY

MNT and DSME/S referrals should be made at the diagnosis of type 2 diabetes, annually, when complications may arise, and when transitions in life occur. Initial treatment recommendations typically include lifestyle modification and possibly medication. Due to the progressive nature of type 2 diabetes, the treatment plan will likely evolve over time to include intensification of medications to optimally manage glucose levels. However, ongoing lifestyle modification and behavioral support continue to be critical components of care and should be integrated with the overall treatment plan through MNT and DSME/S.

KEY POINTS

- Medical nutrition therapy (MNT) is an essential component of treatment for type 2 diabetes. Evidenced-based MNT can improve HbA1c, in addition to preventing, delaying, or treating other comorbidities commonly found with diabetes. Like most aspects of diabetes therapy, care needs to be individualized.

PHYSICAL ACTIVITY

Physical activity is characterized as any body movement that increases energy expenditure above rest, whereas exercise is a planned, purposeful, and often structured form of physical activity. Regular physical activity and structured exercise sessions can improve daily metabolic control, enhance well-being, and reduce cardiovascular risk factors in type 2 diabetes.[26] Aerobic physical activity involves repeated and continuous movement, typically for more than 5 to 10 minutes, of large muscle groups (e.g., walking, cycling, jogging, swimming). Although walking may be the most convenient activity mode, some individuals, because of peripheral neuropathy and/or other physical impairment, may need to perform non weight-bearing activities. Acute aerobic sessions are typically associated with a drop in baseline glucose level and/or a reduction in the postmeal glucose excursion.[26] Resistance or strength-based activities are defined as activities associated with contracting muscles against a load, often using one's own body weight, or by using free weights or resistance bands. These activities can be associated with a transient rise in glycemia,[27,28] perhaps associated with the rise in counterregulatory hormones.[27] Flexibility activities include stretching and/or moving joints through their range of motion, while balance exercises typically include a transfer of body weight to a single limb with or without another touch point. These activities tend not to change glucose levels significantly but are important to help with flexibility and maintaining joint range of motion.[26]

The importance of regular physical activity and structured exercise sessions for people living with type 2 diabetes is often underappreciated. In this population, extended sedentary time and prolonged sitting are associated with poor glycemic control and an enhanced cardiovascular risk profile.[29] Interrupting prolonged siting with some form of physical activity improves postprandial glucose control, insulin sensitivity, and plasma triglyceride levels.[29] Beyond breaking up sedentary time with light activity, exercise training sessions can further improve cardiometabolic outcomes.[26] While consensus guidelines exist for the optimal volume, mode, intensity, and duration of exercise sessions for people living with type 2 diabetes, it should be acknowledged that these recommendations should vary depending on the individual's characteristics, motivations, and current health status.[26] Because individuals with type 2 diabetes typically have a reduced aerobic capacity and a higher rating of perceived exertion,[30] the physical activity prescription may need to be gradually increased from a modest volume at a light intensity (e.g., 10–15 minutes of light walking per day) to a higher volume and a more vigorous intensity (e.g., 45 minutes of brisk walking, jogging, swimming, or cycling), with the addition of other training modes (e.g., resistance training, high intensity interval training [HIIT]) as the tolerance for exercise steadily improves (Table 40.3).

Performing aerobic activities regularly (i.e., three times per week for 20–40 minutes) for 8 or more weeks increase skeletal muscle oxidative capacity, insulin sensitivity, blood vessel reactivity and compliance, capillary density, lung function, immune function, and cardiac performance.[31] Daily engagement in some form of sustained aerobic activity is ideal, because the favorable changes in glucose tolerance and insulin sensitivity typically deteriorate in approximately 24 to 48 hours, depending on the length and intensity of the session.[30] Resistance exercise (i.e., weightlifting) has additive benefits over aerobic exercise and should be performed at least two times per week, using all the major muscle groups (two to three sets of 13 repetitions each).[26] Resistance exercise helps maintain muscle mass, strength, balance, and insulin sensitivity[26] and promotes favorable effects on ambulatory blood pressure and glycemia in the 24-hour period after the session.[32] With weekly aerobic and/or resistance exercise sessions, a lower HbA1c level by 0.5% to 1.0% is typically achieved, along with reductions in

TABLE 40.3 Exercise

	Phase 1	Phase 2	Phase 3	Phase 4
Aerobic				
Duration (min)	10–15	15–20	20–30	30–45
Intensity	Light	Moderate	Somewhat hard	Hard
Frequency (days/week)	3	4	4	5
Resistance				
# of sets per muscle group	1	2	3	3
# of repetitions	10	10	10	8
Intensity (% of 1 repetition maximal	50%	50%	70%	80%
Frequency (days/week)	2	2	3	3
HIIT (optional)*				
Frequency (days/week)			2	3
Min low, minute high, number of cycles			1, 2, 3	2, 2, 5
Intensity (% maximal aerobic capacity during low and high intervals)			40%, 70%	50%, 90%

Exampled phase approach to ramp up the physical activity prescription in individuals living with type 2 diabetes. Each phase may last 2–3 weeks before progressing, if desired. Note: Baseline assessment of physical activity patterns should be performed to determine what phase to initiate. * Note: HIIT can replace one or more aerobic or resistance exercise sessions weekly up to three HIIT sessions per week. *HIIT*, High-intensity interval training.

visceral fat mass, but body weight may not change significantly because of increases in lean mass.[26,30]

The impact that regular physical activity has on cardiovascular mortality in type 2 diabetes is somewhat controversial. A large randomized controlled clinical trial of intensive lifestyle therapy on cardiovascular morbidity and mortality in overweight/obese adults with type 2 demonstrated that lifestyle intervention, which recommended regular physical activity (of at least 175 min/week of unsupervised aerobic activity, along with a low-calorie diet) for a sustained period of time (median 9.6 years) improves glycemic outcomes and cardiovascular risk profile, among several other beneficial effects,[33] including reduced sleep apnea, reduced disability incidence,[34] and enhanced cognitive functioning.[35] However, it is important to note that the incidence of the primary outcome, a composite of fatal or nonfatal myocardial infarction, stroke, hospitalization for angina, or cardiovascular death, did not differ between the intensive lifestyle group and the standard of care group.[33] The intensive lifestyle intervention appeared to reduce cardiovascular events in those who achieved the desired weight loss goal of 7%[36] and in those who had no baseline CVD.[37] Overall, exercise interventions are largely deemed safe and effective with multiple comorbidities associated with diabetes.[38]

HIIT, which is a time-restricted exercise session composed of high- and low-intensity activities lasting anywhere between 6 and 20 minutes, has been demonstrated to have numerous health and fitness benefits in people living with type 2 diabetes.[39-42] However, there is a lack of clarity on whether HIIT is more or less effective (or as safe) as traditional aerobic exercise sessions.[41]

For individuals on insulin or insulin secretagogues, increased physical activity increases the risk for hypoglycemia, including severe hypoglycemia, particularly in settings of weight loss and caloric restriction.[43] As such, lifestyle interventions with exercise should be accompanied with sulfonylurea and/or insulin dose reductions. As noted above, higher intensity effort, as is associated with HIIT, likely reduces the likelihood of exercise-associated hypoglycemia but may result in sustained hyperglycemia if engaged in in the early morning.

KEY POINTS

- Exercise is a key component of treatment for type 2 diabetes and needs to be individualized based on many factors. While daily engagement in some form of sustained aerobic activity is ideal, resistance exercise has added benefits. Exercise interventions are largely deemed safe and effective with multiple comorbidities associated with diabetes.

PHARMACOTHERAPY OF TYPE 2 DIABETES

There are now a range of medications available that effectively reduce blood glucose in persons with type 2 diabetes. Although the expansion of treatment options over the past two decades raises the possibility of widespread improvements to glycemic control, this has not yet been borne out across the population.[44] Moreover, while the differing mechanisms of action among the many agents now on the market suggest potential synergistic combinations, this has not been conclusively demonstrated in general practice or in specific groups of patients. Nonetheless, the variety of options now available to providers is a major advance in diabetes care. The major glucose-lowering medications are reviewed along with their cardiovascular and renal effects (Table 40.4).

Metformin

Metformin has been the consensus choice for initial treatment of type 2 diabetes[45] and should be started at the time of diagnosis in most patients. Metformin has potent glucose-lowering actions, is inexpensive, and may reduce risk of cardiovascular events and death.[46] Although not studied in large randomized trials, observational studies have consistently reported safety of the drug in a wide range of type 2 diabetes patient groups, inclusive of those with major comorbidities.[47] Metformin has little effect on blood glucose in normoglycemic states, does not stimulate the release of insulin or other islet hormones, and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose. Metformin is effective in combination with other glucose-lowering medications for type 2 diabetes, and fixed-dose combinations are available for many of these.

The immediate release form should be titrated to an initial dose of 500 mg twice a day over several weeks to prevent gastrointestinal complaints; there is little therapeutic benefit to using more than 2000 mg daily.

Metformin is cleared by renal filtration, and very high circulating levels (e.g., as a result of overdose or acute renal failure) have been associated with lactic acidosis. However, the occurrence of this complication is now known to be rare, and metformin may be safely used in patients with reduced estimated glomerular filtration rates (eGFR). The US Food and Drug Administration has revised the label for metformin to reflect its safety in patients with eGFR greater than or equal to 30 mL/min/1.73 m^2; dose reduction starting at eGFR of 40 to 50 mL/min/1.73 m^2 is also recommended. Hospitalized patients are at increased risk for acute kidney injury, and metformin should be used cautiously in the inpatient setting.[45] Metformin use is associated with vitamin B12 deficiency, likely the result of abnormal gastrointestinal absorption, and this can compound existing diabetic neuropathy.

TABLE 40.4 **Glucose-Lowering Medications**

Class	HbA1c Reduction	Effect on Weight	Primary Side Effects	Contraindications
Metformin	1%–2%	neutral	Gastrointestinal	eGFR <30 mL/min/1.73 m^2
Sulfonylurea	1%–2%	1- to 3-kg gain	Hypoglycemia	Type 1 diabetes
Thiazolidinedione	0.5%–1%	2- to 4-kg gain	Fluid retention, bone fracture	Heart failure
Glucagon-like peptide 1 receptor agonist	0.5%–1.5%	Weight loss variable—up to 7 kg (semaglutide)	Gastrointestinal in nature	Gastroparesis; some still concerned about pancreatitis
Sodium glucose cotransporter 2 inhibitor	0.5%–0.7%	2- to 4-kg loss	Genital mycotic infection, urinary tract infection	Type 1 diabetes
Dipeptidyl peptidase 4 Inhibitors	0.5%–0.8%	Neutral	Nothing consistent	Heart failure with saxagliptin

eGFR, Estimated glomerular filtration rate.

Thiazolidinediones

Thiazolidinediones are ligands for the PPARγ receptor, a nuclear hormone receptor involved in the regulation of genes related to glucose and lipid metabolism. Only pioglitazone is broadly available to treat type 2 diabetes. Pioglitazone is an insulin sensitizer and increases insulin-mediated glucose uptake by 30% to 50% in patients with type 2 diabetes, primarily in adipose and skeletal muscle. In addition to promoting peripheral glucose disposal, this drug reduces hepatic glucose output. Beyond effects on glucose metabolism, pioglitazone reduces plasma triglycerides by 10% to 15% and raises high-density lipoprotein– and low-density lipoprotein–cholesterol. Pioglitazone has demonstrated consistent effects to reduce hepatic steatosis and nonalcoholic steatohepatitis in affected patients with type 2 diabetes.[48] Finally, pioglitazone significantly reduces the progression of at-risk individuals to type 2 diabetes[49,50] and decreases rates of macrovascular events in high-risk insulin-resistant people at risk for type 2 diabetes.[50]

Pioglitazone is inexpensive and is started at a dose of 15 to 30 mg. It is metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease. Pioglitazone causes weight gain and fluid retention, dose-dependent side effects that can be limiting. Beyond average gains of 2 to 4 kg of fat mass, there is plasma volume expansion; the use of thiazolidinediones requires caution and careful monitoring, and they should not be used in patients with moderate to severe heart failure. Treatment with pioglitazone has been associated with a consistent increased risk of bone fracture in women, with some studies also showing effects in men. Therefore, the presence of osteoporosis and other risks for fracture should be considered before starting this drug. While preclinical studies and observations in treated patients raised the possibility that pioglitazone increased the risk of bladder cancer, recent observational[51] and pharmacoepidemiologic[52] studies suggest that this is not a substantial risk.

Insulin Secretagogues

Agents in this class lower blood glucose entirely through stimulation of insulin release islet β cells. The two subclasses of drugs, sulfonylureas and meglitinides, act by binding the sulfonylurea receptor to trigger ion fluxes in the β cell that promote insulin exocytosis.

Sulfonylureas. Sulfonylureas (SUs) in common usage in the United States include glimepiride, glipizide, and glyburide. These drugs have comparable effectiveness and cause significant glucose lowering in 50% to 80% of people with type 2 diabetes. They are inexpensive and have well-established safety profiles. Chronic administration of SUs leads to an apparent shift in β cell sensitivity to glucose. While secondary failure, i.e., gradual loss of efficacy over months to years of treatment, is a frequently cited concern with SU use, this occurs with most diabetes drugs and is most likely due to the progressive β cell failure that is at the core of type 2 diabetes.[53] Based on the results of prospective treatment studies, treatment with SU reduces microvascular complications due to diabetes.[54]

SUs are generally well tolerated and are available in once-daily formulations that increase compliance. SUs are effective as monotherapy and when combined with other glucose-lowering drugs, including insulin. The SUs have wide dose ranges, but the maximally effective doses are generally lower than the maximum marketed doses. To minimize adverse drug effects, use of low doses of SUs is prudent, with addition of other medications if a therapeutic effect is not realized at a dose 50% of the suggested maximum.

The most common side effects of SUs are hypoglycemia and weight gain. Hypoglycemia due to SUs is the result of β cell stimulation independent of blood glucose, with continued insulin secretion at near euglycemic levels causing continued glucose disposal and impaired counterregulation. Fortunately, severe hypoglycemia is not common,[54] but care is required when treating elderly people or those with significant comorbidities or irregular access to food. Hypoglycemia is dose-dependent, but there is also evidence that glyburide causes higher rates of events than other SUs.

There has long been controversy as to the cardiovascular safety of SU, with an early trial and some metaanalyses suggesting that these drugs increase rates of atherosclerotic CVD (ASCVD) events. However, two recent randomized clinical trials including subjects at high and low risk for CVD demonstrated no difference in major adverse cardiovascular events (MACEs) in subjects treated with SUs or comparators, either linagliptin[55] or pioglitazone,[56] shown in other studies to have no deleterious effect on CVD risk. Thus, at present it is reasonable to conclude that SUs confer neither risk or benefit on cardiovascular risk over a period of 5 years.

Meglitinides. This class of secretagogues is distinct from the SUs in that they do not bind directly to SU receptors, but rather modulate the membrane electrical activity and ion fluxes that are the downstream effectors of SUs. There are two meglitinides: nateglinide and repaglinide. These agents are rapidly absorbed and produce a more rapid but shorter stimulus for insulin secretion. Because of the short duration of action, these medications must be given with each meal, and thus are useful primarily for prandial glucose control. The pharmacokinetics of the meglitinides may also explain the lower rates of hypoglycemia and weight gain than those associated with SUs. Similar to the SUs, there is a minimal glucose-lowering advantage of high doses versus moderate doses of repaglinide.

INCRETIN-BASED THERAPIES

The term *incretin* was originally coined almost 100 years ago to describe factors released by the gut that augment glucose clearance after meals. In recent decades incretin has come to mean insulinotropic gastrointestinal hormones that augment glucose-stimulated insulin secretion. There are two established incretins, glucose-dependent insulinotropic peptide (GIP) and glucagon-like peptide 1 (GLP-1), that account for 50% to 70% of prandial insulin secretion and are necessary for normal glucose tolerance.[57] GLP-1 is a potent insulin secretagogue that also affects blood glucose by delaying gastric emptying, as well as causing satiety. GIP also stimulates insulin secretion, and like GLP-1 does so only when blood glucose levels are elevated. GLP-1 and GIP are rapidly inactivated by the protease dipeptidyl peptidase-4 (DPP-4) that is widely distributed on capillary endothelium; GIP and GLP-1 have plasma half-lives of 7 and 2 minutes, respectively. Currently two approaches have been applied to harness the endogenous incretin system to treat type 2 diabetes[58]: injectable peptides modified for extended residence in the circulation (GLP-1 receptor agonists [GLP-1RAs]), and small molecules that inhibit DPP-4 activity and extend the activity of GLP-1 and GIP (DPP-4 inhibitors [DPP-4i]).

Because GLP-1RAs and DPP4is act through the incretin system, they are frequently discussed as parallel treatment options. In fact, these two subclasses of incretin-based therapies have several major differences. DPP-4is are orally available, increase incretin levels by approximately 2-fold, have only moderate glucose lowering potency, and do not affect body weight, but have very favorable safety and tolerability profiles. GLP-1RAs are administered by injection, raise GLP-1 activity to supraphysiologic levels, are among the most potent glucose-lowering drugs, and cause weight loss, but have common symptomatic side effects.

Glucagon-Like Peptide-1 Receptor Agonists

There are six GLP-1RAs available for use in the United States. Four of these agents are based on the sequence of native GLP-1, modified to reduce inactivation by DPP-4 and extend circulating half-life, and two use exendin-4, an analog of a reptilian peptide that binds the GLP-1 receptor. The most notable differences among these agents are their duration of action, which contributes to both their activity and their dosing frequency. However, because all act through the same specific signaling system, with minimal off-target effects, their pharmacology is broadly shared. All GLP-1RAs stimulate insulin secretion and reduce plasma glucagon, delay gastric emptying and intestinal motility, induce satiety and weight loss, cause modest reductions in blood pressure and increases in heart rate, and are associated with nausea and other gastrointestinal side effects. While there may be some differences among agents in the magnitude of these effects, in any given patient some version this pharmacologic profile can be expected. Recent evidence indicates that GLP-1RAs reduce the risk of MACEs and improve parameters of diabetic nephropathy[59]; it is unclear whether these effects are shared across the class.

The hallmark side effect of GLP-1RAs is nausea, affecting approximately 40% of subjects, with lesser rates of vomiting and diarrhea. Gastrointestinal side effects are dose-dependent, and titration from low to high doses is generally effective in limiting them. Moreover, most patients tend to develop tolerance to the drugs over 2 to 3 weeks of treatment. Treatment with GLP-1RAs does not commonly cause hypoglycemia, but can potentiate this effect when given with SUs or insulin. The exendin-based drugs are renally excreted and should be avoided in persons with advanced renal insufficiency; the GLP-1–based drugs are not renally excreted, but there is limited experience with use in people who have eGFRs below 30 mL/min/1.73 m^2. There is also limited published experience on treating patients with significant hepatic dysfunction with GLP-1RAs, but no consistent adverse effects have been reported. Previous concerns about links between GLP-1RA use and pancreatitis, pancreatic cancer, and metabolic bone disease have been mostly dispelled.[60]

The currently prescribed GLP-1RAs are:

Exenatide is a synthetic replica of the 39–amino acid reptilian peptide exendin-4. Exenatide is a potent GLP-1RA that shares many of the effects of GLP-1. It is not metabolized by DPP-4, and so has extended activity following injection. In acute studies, exenatide reduces prandial blood glucose by augmenting insulin secretion and delaying gastric emptying. Exenatide is approved for use as monotherapy and in combination with other glucose-lowering drugs. Exenatide comes in a short-acting formulation with a plasma half-life of 2 to 3 hours that is injected twice daily in doses of 5 or 10 mcg. There is also a long-acting formulation injected as a suspension of embedded exenatide on a polymeric microsphere that delays absorption, allowing weekly dosing at 2 mg.

In clinical trials, exenatide, alone or in combination with metformin, SU, thiazolidinedione, or basal insulin was associated with an approximately 1% decrease in HbA1c, and weight loss that averaged 2.5 to 4 kg. The extended-release form of exenatide conferred no risk of CVD when evaluated in a randomized cardiovascular outcome trial.[61]

Lixisenatide is the other exendin-4 based GLP-1RA, with short extension that distinguishes it from exenatide. Lixisenatide has similar pharmacokinetics to exenatide but is used as a once-daily injection. It is available for coadministration with insulin glargine in a single-injection pen. Data from a recent cardiovascular outcome trial (CVOT) of diabetic subjects with a prior history of CVD indicated that lixisenatide was safe but did not have beneficial effects to reduce rates of subsequent MACEs.

Liraglutide is a long-acting, DPP-4–resistant form of GLP-1, in which the native sequence is modified by addition of an α-glutamic acid spacer coupled to a C16 fatty acyl group at Lys 26.[61] The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for a half-life of 12 hours, permitting once-daily administration. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide, and chronic use leads to reductions in HbA1c of 1.0% to 1.5% and weight loss of 4 kg. Liraglutide can be added to oral agents or basal insulin. It is administered in 1.2-mg or 1.8-mg doses and is also available for fixed-dose combination administration with insulin degludec.

Liraglutide was the first of the GLP-1RAs to show a significant benefit to reduce MACEs (nonfatal myocardial infarction, or nonfatal stroke, and cardiovascular death) in subjects with established CVD and type 2 diabetes.[62] This finding, and the results of CVOT for other GLP-1RAs, has led to new recommendations favoring the use of these drugs in persons with, or at high risk for, CVD.[63] Liraglutide also reduces the progression of diabetic nephropathy, as marked by proteinuria, in affected patients.[64]

Dulaglutide is a fusion protein consisting of two molecules of a DPP-4–resistant version of GLP-1 linked to the Fc portion of a human immunoglobulin. Attachment to a large carrier protein delays clearance of dulaglutide, and even though it is rapidly absorbed after subcutaneous injection, a protracted circulating half-life allows for once-weekly dosing at 0.75 or 1.5 mg. Average reduction of HbA1c is 1.0% to 1.5%, with weight loss of 2 to 3 kg. Dulaglutide has similar benefits in terms of decreasing MACE and proteinuria as liraglutide.[61]

Semaglutide has a similar structure to liraglutide but differs in two amino acids and the fatty acyl group and linker. These changes increase binding affinity to albumin, giving an extended circulating half-life that allows once-weekly dosing. Semaglutide is the most potent GLP-1RA for glucose lowering, with mean reductions in HbA1c of 1.5% to 2.0% that are greater than those seen with liraglutide and dulaglutide. Semaglutide is also more effective for weight loss, with chronic treatment causing 5- to 7-kg reductions. Semaglutide has similar benefits in terms of decreasing MACE and proteinuria as liraglutide.[61]

Oral semaglutide is now available for clinical use. The active compound is identical to the injectable formulation, but includes a modified fatty acid absorption enhancer to allow passage across the gastrointestinal tract (likely the gastric mucosa). Only approximately 1% of oral semaglutide crosses into the circulation, and the drug must be ingested daily in the absence of food. The oral form of semaglutide has a potency for glucose-lowering and weight loss more comparable to liraglutide than injectable semaglutide, and it shares the beneficial effects on cardiovascular and nephropathic risk reduction.[61]

Dipeptidyl Peptidase Inhibitors

DPP-4 is a widely distributed serine protease expressed as an ectoenzyme on vascular endothelial cells and T-lymphocytes. DPP-4 inactivates a range of peptides, including GLP-1 and GIP, through specific cleavage. DPP-4is increase circulating levels of active, unmetabolized GLP-1 and GIP after meals, and enhanced incretin action is the mechanism of their glucose lowering effect. There are four DPP4is available in the United States: sitagliptin, saxagliptin, linagliptin, and alogliptin. Vildagliptin is available in the European Union and other countries.

Most clinical data suggest that the agents in this class are comparable. Administration causes elevation of active GIP and GLP-1 in the circulation, increases insulin secretion, reduces glucagon levels, and improves both fasting and postprandial hyperglycemia.[63] Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety, nor does chronic treatment with a DPP-4i affect body weight. DPP-4is, used as monotherapy in type 2 diabetic patients, reduce HbA1c levels by an average of 0.5% to 1.0%. These compounds are also effective for chronic glucose control when added to the treatment of diabetic patients receiving metformin, thiazolidinediones, SUs, and insulin, with a further reduction in HbA1c of 0.5%.

There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4is. CVOTs have been completed for alogliptin, saxagliptin, linagliptin, and sitagliptin. There was no impact of these drugs on the incidence of cardiovascular events in diabetic patients; patients treated with saxagliptin had an increase in hospitalization for heart failure. The DPP-4is are renally cleared except for linagliptin, and for the other agents dose reductions are recommended for patients with renal insufficiency.

SODIUM-GLUCOSE COTRANSPORTER-2 INHIBITORS

Sodium-glucose cotransporter-2 (SGLT2) is a sodium-glucose cotransporter located almost exclusively in the proximal portion of the renal tubule. On an average day most humans reabsorb all of the 150 to 200 g of glucose filtered through their kidneys, and SGLT2 accounts for 80% to 90% of this reclamation. The SGLT-2 inhibitors (SGLT2is) were developed to use renal glucose elimination to lower blood glucose. There are currently four SGLT2is inhibitors available for clinical use: canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin. The pharmacologic actions of SGLT2is are targeted and specific, and most clinical data suggests that the agents in this class are comparable. They have relatively long plasma half-lives and can be dosed once daily. SGLT2is can be used as monotherapy and in combination with other oral agents and insulin. Glucose-lowering potency is moderate, with average reductions in HbA1c of 0.7% to 1.0%, and the glycemic effect is dependent on renal function, with the amount of glucose that can be excreted a function of the amount filtered. SGLT2is also decrease blood pressure by 2 to 4 mm Hg and cause an approximately 4-kg weight loss.

The side effects of SGLT2is are predictable from their mechanism of action. There is a small increase in lower urinary tract infections, a 3-fold increase in genital mycotic infections, and mild volume contraction with rare episodes of acute kidney injury.[63] SGLT2is do not cause hypoglycemia but can increase the likelihood when combined with drugs that do. Canagliflozin was associated with a small increase in the risk of fractures and amputations of the lower extremity in a CVOT, but these results have not been observed with other SGLT2is and are not well-established side effects. SGLT2is cause a small but significant increase in diabetic ketoacidosis when given to patients with type 1 diabetes. Diabetic ketoacidosis in persons with type 2 diabetes is reported but rare, and occurs mostly in those treated with insulin, raising the possibility that some of these patients have insulinopenic diabetes.

Recent clinical trials have demonstrated important benefits of SGLT2is in persons with major comorbidities of type 2 diabetes. Empagliflozin, canagliflozin, and dapagliflozin have all demonstrated beneficial effects in lowering rates of MACE.[65] The effects seem to be independent of glucose lowering, and are most pronounced for patients with established CVD, heart failure with reduced ejection fraction, and diabetic nephropathy. In fact, dapagliflozin reduced symptoms, hospitalization, and mortality in patients with reduced ejection fraction who did not have diabetes.[66] Dapagliflozin also reduced progression of renal disease and MACE in a cohort of patients with proteinuria and reduced eGFR.[67] The results of these studies have led to revisions of treatment recommendations from expert panels to favor the use of SGLT2is in patients with established CVD, heart failure, and nephropathy.[68]

α-Glucosidase Inhibitors

α-Glucosidase inhibitors (AGIs) reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border. These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects. The AGIs available in the United States are acarbose and miglitol. AGIs slow the rise of blood glucose by delaying absorption and are indicated as adjuncts to diet and exercise in patients with type 2 diabetes. They can also be used in combination with other oral antidiabetic agents and/or insulin. AGIs do not cause weight gain or have significant effects on plasma lipids. Acarbose reduces the conversion to type 2 diabetes of high-risk persons with impaired glucose tolerance.[69]

Both acarbose and miglitol are given before meals, e.g., two to three times daily. The most prominent adverse effects are malabsorption, flatulence, diarrhea, and abdominal bloating due to the passage of undigested carbohydrate to the lower intestine. Hypoglycemia has been described when AGIs are added to insulin or an insulin secretagogue.

INSULIN THERAPY IN TYPE 2 DIABETES

For the majority of people with type 2 diabetes, the disease is progressive, with a need for increasing intensity of therapy over time.[70] This natural history is thought to be the result of a gradual loss of β cell function and steady decline in insulin production. As other medications lose efficacy with the progression of diabetes, insulin becomes the treatment of last resort, an agent that can replace and compensate for the loss of endogenous insulin production.[71]

Over the last 30 years there have been several major advances in insulin chemistry and formulation that have greatly expanded the options for glycemic management. Porcine and bovine insulins, the standard of care for the first seven decades of insulin use, were replaced by human insulins, regular and neutral protamine Hagedorn (NPH), made by recombinant genetic methods. Subsequently, a number of insulin analogs were developed,[72] each with distinct physicochemical properties that altered their pharmacokinetics and provided a range of onset and duration of activities.

Human regular insulin. Native, or regular, insulin molecules associate as hexamers in aqueous solution at a neutral pH, and this aggregation slows absorption following subcutaneous injection. Regular insulin is generally used to promote glucose control during meals but is slower than the rapid-acting analogs (Table 40.5). The optimal use of regular insulin for prandial coverage is to inject 30 minutes before a meal.

Human NPH insulin. NPH insulin is a suspension of native insulin complexed with zinc and protamine, causing a cloudy solution that contrasts with the clear appearance of other insulins. NPH insulin dissolves more gradually when injected subcutaneously, and thus its duration of action is prolonged (Table 40.5). NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with a prandial insulin before breakfast and supper.

Short-Acting Insulin Analogs

There are three of these insulins available, insulin lispro, insulin aspart, and insulin glulisine, which have similar characteristics and clinical efficacy (Table 40.5). More recently, somewhat faster analogs of insulin aspart and lispro have been released, but the clinical impact of this is unclear. Each has one or more amino acid substitutions that limit the natural aggregation into hexamers. As a result, all are absorbed more rapidly from subcutaneous sites than regular insulin and can be injected approximately 10 minutes before a meal.

Long-Acting Insulin Analogs (Table 40.5)

Insulin glargine is a long-acting analog of human insulin. Three substitutions in the amino acid sequence shift the pH for solubility of glargine to 4.0, which stabilizes the insulin hexamer. When injected into the neutral pH of the subcutaneous space, insulin glargine aggregates, with slow dissolution and steady, predictable absorption from the injection site. Clinical trial data suggest that glargine has a modestly lower risk of nocturnal hypoglycemia compared with NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy.

Insulin detemir is an insulin analog modified by the addition of a saturated fatty acid to the molecule that allows binding to albumin and a prolonged half-life in the circulation.

Insulin degludec is a modified insulin with one amino acid deleted and a long-chain fatty acid bound to the amino acid chain. Degludec forms multihexamers after injection subcutaneously and dissolves slowly.

Concentrated insulins. Several concentrated insulin preparations are currently available. U-500 (500 units/mL) regular insulin is, by definition, five times more concentrated than the standard U-100 (100 units/mL) formulation. Regular U-500 has distinct pharmacokinetics that are closer to NPH insulin, in duration of action, but can still be used as a prandial insulin. U-300 glargine and U-200 degludec are three and two times as concentrated as their U-100 formulations, and a U-200 formulation of insulin lispro is available. These concentrated preparations may provide more consistent absorption and less discomfort for patients who require large amounts of insulin, because the volume of injection is smaller. All concentrated insulins are now available in prefilled pens to minimize the risk of dosing errors.

Premixed insulins. Premixed insulin formulations include a 70/30 mixture of regular and NPH insulin, a 75/25 mixture of lispro and NPH, and a 70/30 mixture of aspart and NPH. These insulins have advantages in convenience because they can deliver prandial and basal insulins with a minimum of injections. The activity profiles of these insulins are the sum of the constituents, with superimposed faster and longer-acting components. These insulins are typically given twice daily before the morning and evening meals.

Insulin Dosing and Regimens. While insulin may be the first drug initiated to treat people with type 2 diabetes, particularly those who present with very high blood glucose, symptoms of glucosuria, and weight loss, for most patients it is added later in the treatment regimen. A common strategy is to add basal insulin to oral agents in patients who need more glucose lowering. Starting doses can be estimated based on body weight (0.1–0.2 units/kg/day) and the degree of hyperglycemia. The principal action of basal insulin is to restrain hepatic glucose production and limit hyperglycemia overnight and between meals, so titration of dose is usually based on the fasting glucose level.

Many individuals with type 2 diabetes will also require doses of insulin before meals. While this typically becomes necessary for

TABLE 40.5 Insulin: Pharmacokinetics of Insulin Preparations

Insulin Type	Approximate Onset of Action	Peak Effect	Approximate Duration of Action[*]
Regular	30–60 min	2–4 hours	5–8 hours
NPH	1–2 hours	2–8 hours[*]	14–24 hours[*][†]
Lispro, lispro-aabc, aspart, faster aspart, glulisine	15–30 min	45–75 min[‡]	3–5 hours[‡]
Glargine	2–4 hours	Minimal	20–24 hours[†]
Detemir	2–3 hours	3–8 hours[†]	8–24 hours[‖]
Degludec	Not applicable	None	>40 hours

[*] May vary considerably

[†] Extremely dose-dependent

[‡] Lispro-aabc and faster aspart generally faster and shorter duration

[‖] Duration is dose-dependent. At higher doses (≥0.8 units/kg), mean duration of action is longer and less variable (22 to 23 hours)

NPH, Neutral protamine Hagedorn.

(Adapted from Hirsch IB, Juneja R, Beals JM, et al. The evolution of insulin and how it informs therapy and treatment choices. *Endo Rev.* 2020;41:733–755.)

patients with long duration of diabetes, it may be needed early in the course of treatment in some, often relatively lean, people whose type 2 diabetes is due to significant loss of β cell function. For the more typical patients with obesity as a comorbidity, insulin resistance is a central aspect of the pathophysiology of type 2 diabetes, and the average dose of insulin required for these patients is often above 1 u/kg. Prandial dosing can be safely started at 10% of the amount of basal insulin at each meal; optimized regimens usually include 40% to 50% of the total daily dose as prandial insulin. Premeal insulin can be titrated to blood glucose levels before the next meal. Doses can be adjusted based on carbohydrate content, or simply meal size. It is also common to add insulin to the prandial dose based on the premeal blood glucose value, a correction dose.

Adverse events. Hypoglycemia is the major risk of insulin use that must be weighed against the benefits of improved glucose control. Risk of hypoglycemia varies widely among persons with type 2 diabetes, with patients who have lower body weights, are more insulin sensitive, or have comorbidities such as renal and hepatic insufficiency or impaired cognition being more susceptible. In patients with higher body mass index and insulin resistance, hypoglycemia is less common. Insulin treatment is associated with modest weight gain, usually 2 to 4 kg. It is not uncommon to see patients who have been poorly controlled, with elevated HbA1c, glucosuria, and weight loss, gain 8 to 10 kg as their blood glucose is brought under control with insulin.

PRACTICAL ASPECTS FOR MANAGING TYPE 2 DIABETES

Glucose lowering is the specific challenge of diabetes management, and the steady expansion of drug classes providing distinct mechanisms to treat hyperglycemia provides a range of options that can be fit to particular patient needs. The first step in glycemic management is setting a target that is appropriate for individual patients, incorporating their capacity and resources for care, health goals, disease duration, established diabetes complications, comorbidities, and specific predilection for drug side effects.[73] There is now abundant evidence that hyperglycemia is the major modifiable risk for microvascular disease and neuropathy.[74] Based on clinical trials, a goal of reducing HbA1c to 7% or less is a reasonable standard for patients in whom microvascular disease prevention is a priority. For this group of generally younger people without established diabetes comorbidities, the benefit of intensifying treatment to hit a lower glycemic target outweighs the burden of drug side effects, medication costs, and the greater patient effort for self-care. For older patients with longer duration of diabetes, established microvascular disease, or serious comorbidities, the risk-to-benefit ratio for intensive treatment may be different. Setting the glycemic goal (usually an HbA1c target) is an important and useful point of discussion with patients and should be revisited over their course of care.

Although the number of medications available to treat diabetes has grown rapidly in recent years, clear evidence as to their optimal use has lagged. There is reasonable evidence on which to base initial therapy and for the stepwise addition of medications to maintain glycemic targets. There is also increasing evidence for the benefits of using some drugs, SGLT2is and GLP-1RAs preferentially, in patients with increased risk for CVD and renal disease. However, there are not yet clear algorithms for glycemic management that can be broadly applied. Each class of drugs has advantages and drawbacks, and the clinical issues for patients with type 2 diabetes are heterogeneous, so treatment must be individualized. Recent statements from expert panels provides some guidance and order to glycemic treatment.[63]

Initial Therapy (Fig. 40.1)

Metformin remains the preferred initial glucose-lowering medication for most people with type 2 diabetes and should be added to lifestyle measures in newly diagnosed patients. This recommendation is based on efficacy, safety, tolerability, low cost, and extensive clinical experience. Results from a substudy of the UK Prospective Diabetes Study showed benefits of initial treatment with metformin on clinical outcomes related to diabetes, with less hypoglycemia and weight gain than with insulin or SUs.[75] In type 2 diabetes patients started on metformin, maintenance of blood glucose in the target range wanes over the course of several years.[53] Thus, it is common for additional medications to be added to metformin as this occurs; all other available medications for glucose lowering have been studied in combination with metformin.

An important consideration when initiating therapy is the approach to patients with severe hyperglycemia (glucose >300 mg/dL; HbA1c >10 %), with symptoms of hyperglycemia, and/or or with evidence of ongoing catabolism.[71] This constellation of symptoms can occur in type 2 diabetes, but raise the possibility of significant insulin deficiency and the possibility that the patient has autoimmune (type 1) or pancreatic diabetes (type 3c). In these patients, using insulin as the initial treatment is often the most prudent approach. Often people who have type 2 diabetes can be transitioned to oral medications once their initial hyperglycemia is treated, but using insulin when some question exists about the diagnosis and physiology of an uncontrolled patient prevents further decompensation.

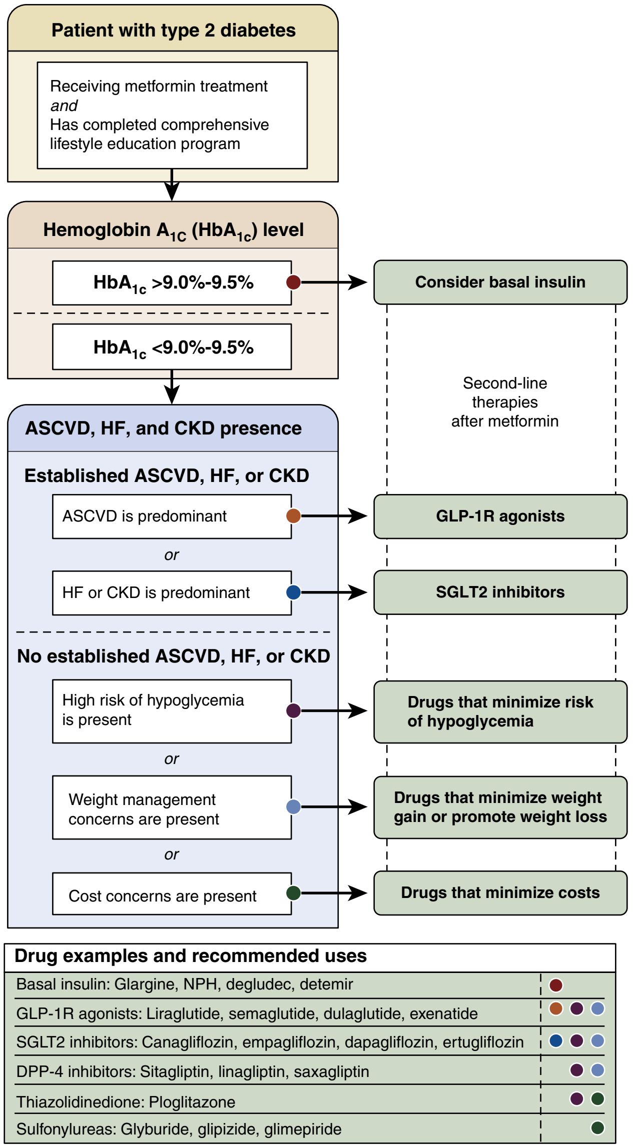
Initial Combination Therapy

The stepwise addition of glucose-lowering medication has been favored over initial combination therapy for most patients. Stepwise therapy (i.e., adding medications to metformin to maintain HbA1c at target) is supported by clinical trials.[45] While there is some support for initial combination therapy due to the greater initial reduction of HbA1c than can be provided by metformin alone, there is only limited evidence that this approach is superior to sequential addition of medications for maintaining glycemic control or slowing the progression of diabetes. However, because the absolute effectiveness of most oral medications rarely exceeds a 1% HbA1c reduction, initial combination therapy may be considered in patients presenting with HbA1c levels more than 1.5% above their target. Potential benefits of combination therapy need to be weighed against the exposure of patients to multiple medications and potential side effects, increased cost, and, in the case of fixed combination medications, less flexibility in dosing.

Addition of Medications for Patients Not Achieving Glycemic Targets

The selection of medication added to metformin will vary among patients based their preferences and clinical characteristics (Fig. 40.1). Important considerations include the presence of established ASCVD and other comorbidities such as heart failure or chronic kidney disease; the risk for specific adverse medication effects, particularly hypoglycemia and weight gain; and safety, tolerability, and cost.

1. *Patients with cardiovascular or renal disease.* Evidence from clinical trials supports the use of SGLT2is and GLP-1RAs as early add-on therapy for people with type 2 diabetes and at high risk for CVD, heart failure, or diabetic nephropathy.[68] GLP-1RAs reduce cardiovascular events in people with established coronary disease or multiple risk factors for coronary artery disease. There is similar data for SGLT2is, and these drugs appear to be particularly effective in people with heart failure and proteinuric renal insufficiency. Both GLP-1RAs and SGLT2is decrease the progression of diabetic kidney disease. The mechanisms by which these two classes of drugs mediate



Patient with type 2 diabetes
Receiving metformin treatment
and
Has completed comprehensive lifestyle education program
Hemoglobin A1C (HbA1c) level
HbA1c >9.0%-9.5%

SGLT2 inhibitors: Canagliflozin, empagliflozin, dapagliflozin, ertugliflozin ● ● ●
DPP-4 inhibitors: Sitagliptin, linagliptin, saxagliptin ● ●
Thiazolidinedione: Pioglitazone ● ●
Sulfonylureas: Glyburide, glipizide, glimepiride ●

ASCVD indicates atherosclerotic cardiovascular disease; CKD, chronic kidney disease; DPP-4, dipeptidyl peptidase 4; GLP-1R, glucagon-like peptide 1 receptor; HF, heart failure; NPH, neutral protamine Hagedorn; SGLT2, sodium glucose contransporter 2.

Fig. 40.1 Proposed approach for earlier initiation of insulin therapy for patients with type 2 diabetes.

beneficial effects on diabetic complications are not yet established, but appear to be independent of glucose lowering. There are ongoing debates about whether SGLT2is and GLP-1RAs should be used more broadly or targeted to the patient groups that benefit most, but the effects of these agents on the consequences of macrovascular and microvascular disease adds a new dimension to diabetes care.

2. *Patients at risk for common side effects of glucose-lowering drugs.* SUs and insulin are associated with an increased risk for causing hypoglycemia and are often avoided for persons in whom this is an especially serious complication, i.e., the aged, infirm, those with renal insufficiency, or those with impairment of cognition and mental status. Insulin and SUs, as well as pioglitazone, are associated with weight gain; because it is common for people with type 2 diabetes to struggle with obesity, this side effect is problematic for many. In subjects trying to reduce body weight, the weight loss provided by SGLT2is and GLP-1RAs can be useful.
3. *Cost.* Even in countries with advanced healthcare systems, the cost of drug acquisition is increasingly passed to patients. Thus, drug costs are a major concern for a substantial portion of the population of people with diabetes. Drug costs are especially relevant for diabetic patients because of the many medications they usually use and their generally long duration of treatment. Failure to recognize this issue in practice can lead to patient stress, financial hardship, nonadherence, and poor outcomes. The least expensive glucose-lowering drugs are SUs, metformin, pioglitazone, and human insulins; brand-name agents (GLP-1RAs, SGLT2is, and DPP4is) are considerably more expensive.

Intensification of treatment beyond dual therapy to maintain glycemic targets requires consideration of the impact of medication side effects on comorbidities, as well as the burden of treatment and cost. The lack of a substantial response to one or more noninsulin therapies should raise the issue of adherence and, in those with weight loss, the possibility that the patient has autoimmune (type 1) or insulinopenic diabetes. However, it is common for people with longstanding diabetes to require more than two glucose-lowering agents, often including insulin. Compared with the knowledge base guiding dual therapy of type 2 diabetes, there is even less evidence guiding these choices.[63] In general, intensification of treatment beyond two medications follows the same general principles as the addition of a second medication, with the assumption that the efficacy of third and fourth medications will be somewhat less than additive.

No specific glucose-lowering drug combinations have demonstrated consistent superiority over others, with the exception of insulin plus a GLP-1RA. This combination is particularly potent, and the weight loss effects of the GLP-1RA tend to blunt weight gain from insulin. As more medications are added, there is an increased risk of adverse effects.

While most patients require intensification of glucose-lowering medications, some may require medication reduction or discontinuation, particularly if the therapy is ineffective or is exposing patients to a higher risk of side effects, or when glycemic goals have changed, e.g., due to new or worse comorbidities or even healthy aging. A guiding principle is that, for all therapies, the response should be reviewed at regular intervals, including the impact on efficacy (HbA1c, weight) and safety; the therapy should be stopped or the dose reduced if there are minimal benefits or if harm outweighs any benefit.

KEY POINTS

- Pharmacotherapy for type 2 diabetes has dramatically evolved into a more personalized approach from past eras. The decision to use a particular agent is based on glycemic control, the presence or absence of atherosclerotic cardiovascular disease, heart failure, or renal disease, and concerns about weight, hypoglycemia, and cost.

DIABETES TECHNOLOGY

Diabetes technology continues to rapidly expand. Traditionally, this term has encompassed mechanisms of insulin administration, including continuous subcutaneous insulin infusion (CSII)/pump therapy and devices that monitor blood glucose either by meter or continuous glucose monitoring (CGM). However, as pumps and CGM integrate and digital technology increases, diabetes technology now also includes the software that carries out this integration, programs/applications that help facilitate patient self-management, patient and provider engagement, and even virtual access /direct care through telemedicine. Similar to the concept of personalized HbA1c, diabetes technology should be individualized for each patient. As well, it is important to highlight that diabetes technology is advancing so quickly that the literature is often obsolete as new technology comes to the market and published research lags behind innovation.[76,77]

Self-Monitoring of Blood Glucose

In clinical practice, self-monitoring of blood glucose (SMBG) is considered a key component of self-management and treatment in patients with type 2 diabetes irrespective of insulin use. This is especially true when SMBG is prescribed as part of a DSME/S program. However, based on the evidence, there is controversy about the benefit of SMBG in type 2 diabetes. Structured self-monitoring has been showed to modestly reduce HbA1c only in some studies.[78] In patients not receiving insulin, a recent randomized study showed no benefit with SMBG,[79] but a more current metaanalysis revealed improvement in both HbA1c and body mass index when SMBG frequency was greater than eight times per week.[80] The potential cost and burden to patients with frequent glucose monitoring without clear advantage highlights the need to tailor SMBG to each individual. SMBG testing may be most helpful when altering lifestyle factors such as diet and physical activity. SMBG is also particularly helpful with initiation/titration of medications that can cause hypoglycemia. For example, although studies have not showed benefit for SMBG testing in those taking basal insulin, there is evidence that measuring fasting glucose in order to titrate insulin dosage lowers HbA1c.[81] Overall, SMBG use should be reevaluated at each visit, and patients should be empowered by their clinician to understand SMBG data in order to optimize lifestyle and pharmacologic therapy.

Continuous Subcutaneous Insulin Infusion Systems, "Smart" Pens, and Continuous Glucose Monitoring

CSII delivers hourly rapid-acting insulin (basal insulin) and allows the user to deliver mealtime insulin (bolus dose) according to oral intake and current blood glucose levels. There are now also hybrid/partially closed looped systems that both monitor glucose and deliver insulin based on glucose and predicted glucose. To date, there are no studies assessing these more sophisticated pumps in type 2 diabetes.

V-Go is a simple CSII system that is reapplied every 24 hours and gives prefixed hourly basal insulin the ability to mechanically administer bolus insulin.[82] InPen is an insulin pen with an app that helps patients calculate mealtime insulin doses and records insulin use for providers to review with their patients.[83] Although clinically useful and theoretically promising, there have been no studies looking at glycemic improvement compared with standard insulin delivery systems in patients with either type 1 or type 2 diabetes for either the V-Go or this first "smart" pen.

For type 2 diabetes and CSII, there are only data with older technology. A metaanalysis of patient-level data for participants with suboptimally controlled type 2 diabetes and CSII or multiple daily doses of insulin (MDI) showed a small but statistically significant reduction in HbA1c (by 0.4%) with a more impressive 26% reduction of insulin dose in those on CSII.[84] A more recent metaanalysis failed to show a difference between CSII and MDI and reported that pump therapy was only possibly associated with a lower hypoglycemia risk.[85] Limited use of CSII pump in this population is expected, especially as there is more use of the newer insulin-sparing agents.

Although utilization of pumps is uncommon in type 2 diabetes, CGM use is expanding. CGMs are devices that measure interstitial glucose. CGMs correlate well with plasma glucose and provide up to 288 glucose readings every 24 hours. There are two basic types of CGM devices: retrospective/professional and real-time. Retrospective/professional CGM devices blind patients to blood glucose data. Conversely, real-time CGMs can have automated alarms based both on current and predicted changes in glucose. Flash/intermittent scanned CGM (isCGM) technology is a type of CGM that measures levels continuously, but the patient must chose to scan to reveal glucose levels and their trend.

CGM now has implantable technology where the user can have a small device implanted in their arm. There is also a standard report called the ambulatory glucose profile, and CGM metrics goals have been established[76] (Fig. 40.2).

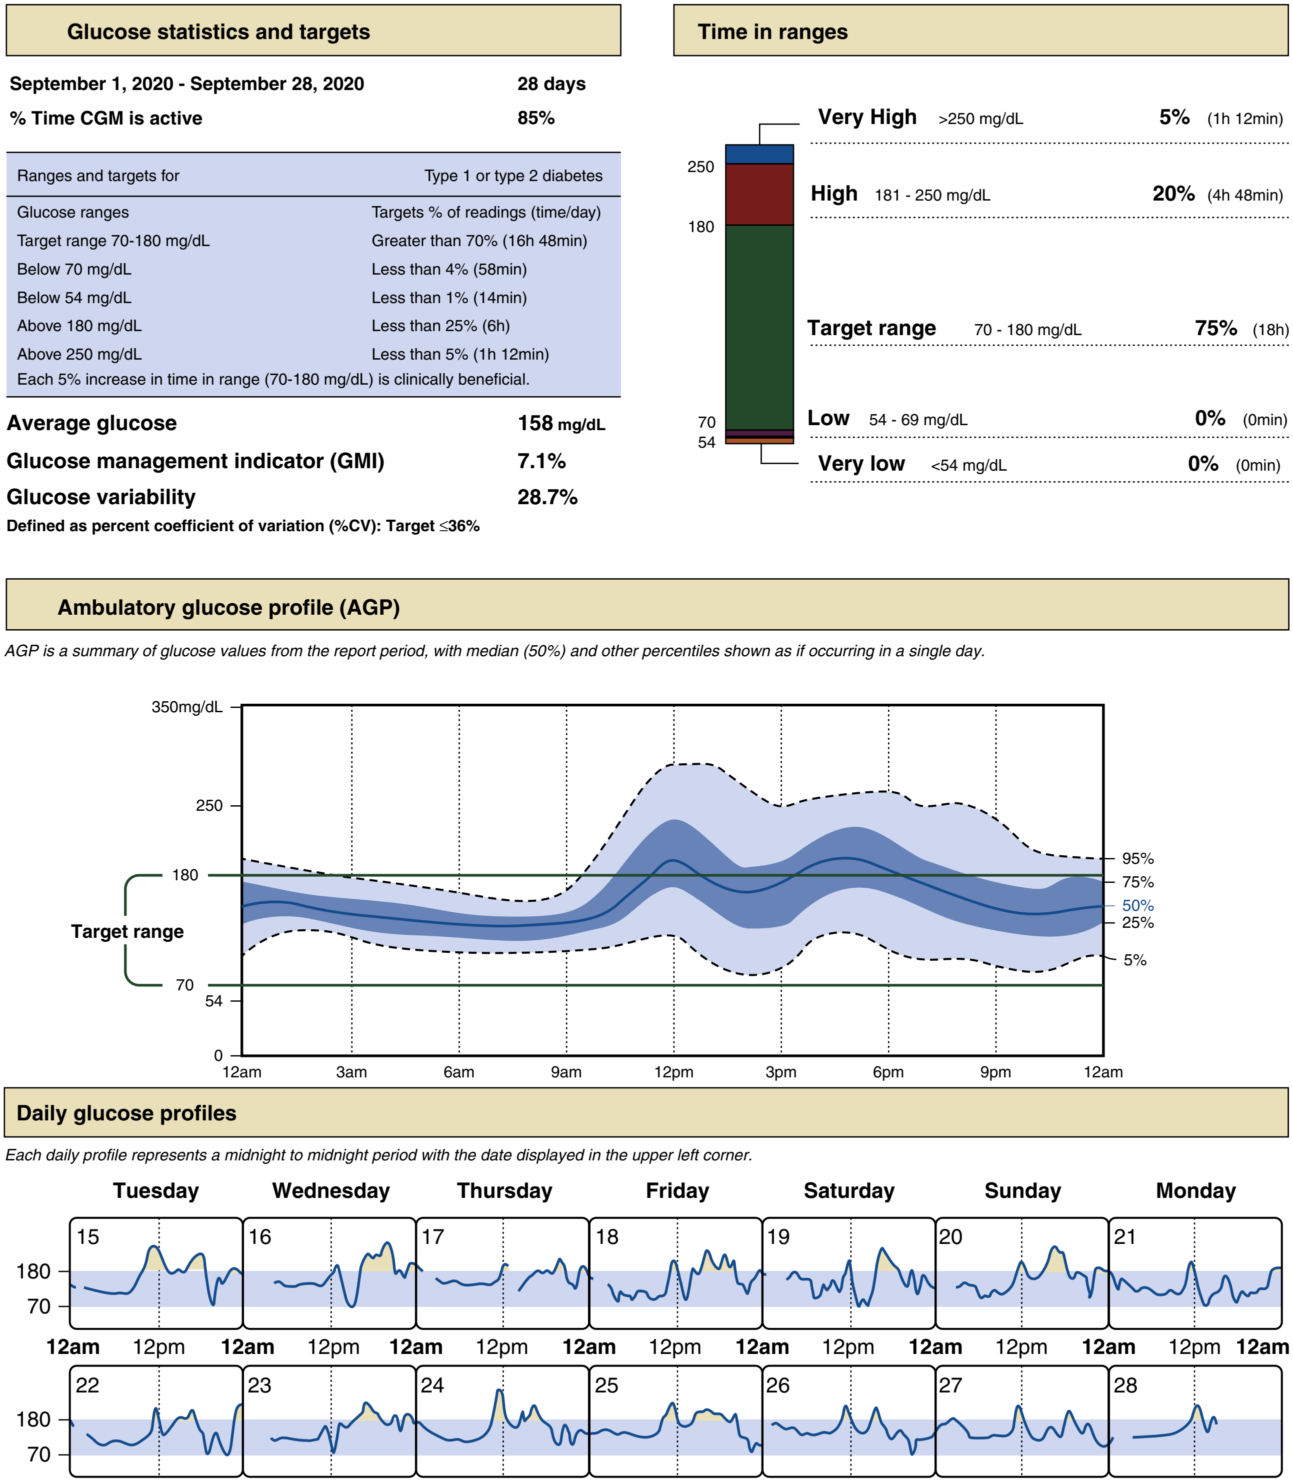
CGM studies in patients with type 2 diabetes are limited. There is only one completed study which used the most updated CGM technology and whose participants were not on MDI. This recent RCT was in an ethnically diverse population only on basal insulin and other insulin-sparing agents and did show a benefit from RT-CGM use. Mean HbA1c level decreased from 9.1% at baseline to 8.0% at 8 months in the CGM group and from 9.0% to 8.4% in the BGM group (adjusted difference, −0.4% [95% CI, −0.8% to −0.1%]; P = .02).[120] The three largest and most recent studies have primarily assessed those receiving intensive insulin therapy with type 2 diabetes. The Multiple Daily Injections and Continuous Glucose Monitoring in Diabetes (DIAMOND) study using real-time CGM showed a statistically significant 0.3% reduction in HbA1c ($P = 0.022$) compared with control, and importantly there were no significant changes in hypoglycemia.[86] Conversely, isCGM demonstrated a decreased duration of hypoglycemia ($P = 0.0014$) but did not result in a significant change in HbA1c.[87] Finally, in the most recent isCGM study in individuals with type 2 diabetes on MDI, there was a 0.49% greater HbA1c reduction in the CGM group ($P = 0.005$), with no significant change in rates of hypoglycemia.[88] Overall, a recent metaanalysis comparing SMBG and CGM showed only marginal significance favoring CGM (−0.24%; $P = 0.05$).[85]

There is also paucity of data in patients using CGM who are not receiving MDI therapy and are only receiving basal insulin and/or oral agents. Two studies that excluded patients receiving prandial insulin did show meaningful reduction in HbA1c levels[89,90]; the larger study used cyclical real-time CGM for 12 weeks (2 weeks on with 2 weeks off) and found a 0.5% greater reduction in HbA1c at 12 weeks ($P = 0.006$).[90] At 52 weeks there was a sustained glycemic effect with no intensification of medical management.[91] There are only a few small studies that have assessed how CGM influences nutritional and physical activity, with some positive findings, but the data are limited.[92]

CGM use in type 2 diabetes continues to expand with rapidly changing technology and aggressive marketing. Hopefully with patients' growing awareness of CGM and continued technology innovation, more type 2 diabetes patients will have access to CGM, and more research will better define the role of this technology for type 2 diabetes.

Digital Health Technology

Digital health technology for diabetes management is also rapidly expanding and continuously evolving. Literature has shown some benefit for everything from automated telephone, web, and internet delivery of education, mobile/digital applications ("apps"), and even videogames, gamification, and virtual environments in the self-management of diabetes.[93] The technology that has grown the most rapidly is probably mobile health apps for diabetes. For example, apps that allow glucose meters to pair with a phone are now common, as are apps that combine meter data with active diabetes and lifestyle coaching. These apps help with self- management and target nutrition, physical activity, glucose monitoring, insulin titration, and delivery.[94,95] A recent survey showed that one third of patients with type 2 diabetes queried were using apps and also found that, after adjusting for confounding factors, diabetes app use increased confidence in diabetes self-management (cumulative self-care score 1.18 [95% confidence interval: 0.26–2.09]).[96] However, across the United States and Europe, mobile apps intended to manage diabetes are largely unregulated. There is inadequate evidence on app accuracy and clinical validity, with



Glucose statistics and targets

September 1, 2020 - September 28, 2020	**28 days**
% Time CGM is active	**85%**

Ranges and targets for	Type 1 or type 2 diabetes
Glucose ranges	Targets % of readings (time/day)
Target range 70-180 mg/dL	Greater than 70% (16h 48min)
Below 70 mg/dL	Less than 4% (58min)
Below 54 mg/dL	Less than 1% (14min)
Above 180 mg/dL	Less than 25% (6h)
Above 250 mg/dL	Less than 5% (1h 12min)

Each 5% increase in time in range (70-180 mg/dL) is clinically beneficial.

Average glucose	**158 mg/dL**
Glucose management indicator (GMI)	**7.1%**
Glucose variability	**28.7%**

Defined as percent coefficient of variation (%CV): Target ≤36%

Time in ranges

Very High	>250 mg/dL	**5%**	(1h 12min)
High	181 - 250 mg/dL	**20%**	(4h 48min)
Target range	70 - 180 mg/dL	**75%**	(18h)
Low	54 - 69 mg/dL	**0%**	(0min)
Very low	<54 mg/dL	**0%**	(0min)

Ambulatory glucose profile (AGP)

AGP is a summary of glucose values from the report period, with median (50%) and other percentiles shown as if occurring in a single day.

Daily glucose profiles

Each daily profile represents a midnight to midnight period with the date displayed in the upper left corner.

Fig. 40.2 Ambulatory glucose profile. (From Battelino T et al. Clinical targets for continuous glucose monitoring data interpretation: recommendations from the International Consensus on Time in Range. Diabetes Care, 2019 Jun. https://doi.org/10.2337/dci19-0028.)

concern over insufficient data security and poor interoperability and standardization. These issues lead to the ongoing questions regarding how to regulate this digital technology and if clinicians should recommend this potential helpful tool in diabetes management.[94]

Telemedicine:

Telemedicine has a broad definition that encompasses both virtual direct care by specialists (teleconsultation) and remote monitoring and feedback through digital technology (telemonitoring). Telemedicine has demonstrated good patient satisfaction scores, specifically for education and management, and has been shown to reduce cost and improve access to diabetes care.[97] A recent metaanalysis specific to remote monitoring of diabetes and self-care found modest reductions in weight and HbA1c,[98] as did another metaanalysis that included both teleconsultation and telemonitoring, concluding that it was especially effective in older patients with type 2 diabetes and with longer program duration.[99] “Parity” laws in 2016 mandating reimbursement for telemedicine passed in 32 US states and created significant growth in primary care and tele–mental health but not tele–endocrine health.[100] Currently, everything from retinal screening[101] to The Diabetes Prevention Program Classes[102] are available remotely. Until recently, telehealth visits for diabetes were not evolving at the same rate as available technology.[100] Typical care for diabetes has drastically changed secondary to the SARS-Cov-2 virus. Telemedicine for diabetes is now increasing rapidly, given the needs of the patients and reimbursement available to providers.[103-104] In this new “landscape” for healthcare systems, telemedicine will continue to evolve to support diabetes patient care.

KEY POINTS

- Diabetes technology has had tremendous growth for the treatment of type 2 diabetes. While self-monitoring of blood glucose is still considered a key component of self-management and treatment, there is growing interest in the use of continuous glucose monitoring, particularly for those receiving insulin therapy. Digital diabetes health is growing rapidly, assisting the rise in the use of telemedicine.

POPULATION MANAGEMENT

With the rising prevalence of diabetes in the population,[105] the skyrocketing costs of diabetes medications,[106] and the shrinking number of diabetes specialists,[107] a new paradigm for the clinical care of diabetes patients has evolved in the form of population management. Population management is a tool for managing chronic diseases at the health system level that focuses on health outcomes of a group of individuals, including the consideration of how the outcomes are distributed within the group.[108] Population management utilizes the following key components: 1) disease registries that allow patients to be identified proactively, 2) electronic health records utilized for both individual and population care, 3) evidence-based treatment protocols and decision support tools, 4) self-management support, 5) team-based diabetes care, and 6) a focus on patients at risk for poorer outcomes.[108,109]

The concept of population management originated in the 1990s when Ed Wagner and colleagues proposed the “Chronic Care Model,” a model that aimed to improve health outcomes by shifting care processes from acute and reactive to proactive and population-based.[110] In an acute care, or “sick care,” system healthcare providers rely on patients to present to the clinic with symptoms, the provider recommends a treatment, and there is very little emphasis placed on the patient’s overall health, prevention of disease or complications, or continuity of care across providers, because these care aspects are not incentivized for the busy provider. Effective chronic disease management necessitates a different approach, in which individual health care is planned, ongoing, integrated, and evidence-based. In this setting, health promotion and prevention strategies target the entire population, not just the patient who walks into the office, with a focus on higher risk groups. This approach, termed “population management,” requires moving from a reactive to a proactive care delivery system and enables the system to achieve two important goals: improved patient outcomes and cost-effectiveness.

The first central feature of a population management program is a means of identifying patients who need care, by way of a comprehensive disease registry.[111] This is a list of all patients within the health system (at the individual level) with a diagnosis of diabetes, derived from diagnosis codes, prescription data, and/or lab results. The registry can be greatly enhanced with the inclusion of electronic medical record (EMR) data in the registry output such as HbA1c values, last eye exam, blood pressure, smoking status, and statin use. This output can highlight care gaps, and it can also permit sorting and prioritizing to identify patients with care gaps for proactive outreach (e.g., retinal exam is due) or track population-level outcomes (e.g., what proportion of diabetes patients have uncontrolled blood pressure).[112]

Another key component of population management that is enabled by a disease registry and an EMR includes the use of a simple evidence-based treatment protocol that provides primary doctors with evidence-based, guideline-concordant support at the point of care.[111] This protocol can be used to design and implement technology tools, such as best practice alerts (e.g., electronic prompts to the provider that an HbA1c is due), or decision-support tools in the form of clinical calculators that pull data from the EMR (e.g., risk calculators for CVD).

Team-based care is a fourth key feature of a population management program.[111] The multidisciplinary care team may include a primary care physician, medical assistant, nutritionist, nurse, pharmacist, health educator, behavioral medicine specialist, endocrinologist, ophthalmologist, nephrologist, cardiologist, and/or podiatrist. Not only does team-based care allow for providers to work at the top of their licenses, but it also has been shown to improve patient outcomes[113] and reduce costs.[114] Team-based care, in conjunction with technology tools, can also be used to ensure that patients are effectively managed between visits with their primary doctor. For example, remote glucose monitoring systems that provide inbox notifications when patients are having glycemic issues at home can enable midlevel providers to reach out by phone, video, or secure message to intensify treatment and avoid significant glycemic deterioration, rather than waiting 3 to 6 months for a HbA1c result to indicate a problem. This proves a particularly effective strategy for “virtually” helping diabetes patients achieve good outcomes in the setting of a pandemic like COVID-19.

One facet of population care that poses both a challenge and an opportunity is the ability to address health disparities, i.e., to target groups that are at higher risk for disease complications to receive earlier or more aggressive interventions. Diabetes and diabetes complications disproportionately affect vulnerable subgroups, including economically disadvantaged persons and some racial minorities.[115,116] While population care strategies can have dramatic effects on reducing diabetes complications, morbidity, and mortality in a population as a whole, this type of systemic, standardized approach has the potential to leave out those who are not engaged with the healthcare system, leading to increases in racial/ethnic disparities in health outcomes.[117] Thus, the health system needs to strike a careful balance between individual needs and population needs. On the flip side, population care also presents opportunities to reduce health disparities by using systems-level mechanisms to screen for social determinants of health (e.g., potentially vulnerable groups can be identified by demographic, socioeconomic, and language information available in the EMR) and providing this information to care teams to outreach to at-risk subpopulations and provide culturally and linguistically appropriate care[117] in order to both reduce disparities and improve overall quality of care.[118]

One major challenge in implementing a population management strategy in a fee-for-service practice environment, such as the one present in many parts of the United States, is the disconnect between payments for “sick care” management versus those for preventative care or chronic disease management. Implementing effective population management requires that healthcare resources be shifted upstream, to fund registries and EMRs, invest in technology tools, enable team-based care, and support outreach efforts—endeavors that may not be fully reimbursed in the fee-for-service care model.

External incentives have helped to move some systems in the direction of population management,[119] but reimbursement concerns remain a reality for many healthcare providers in fee-for-service practices. Ideally, resources are shifted even further upstream, to support and strengthen the existing public health infrastructure and to address social determinants of health at a societal level. As we think towards the future, we need to ensure that population-based approaches to diabetes care are well-aligned with current healthcare policies and that best practices in diabetes population care are disseminated in ways that increase both the accountability and patient-centeredness of the healthcare system, as well as reducing racial and ethnic disparities in healthcare outcomes.[109]

KEY POINTS

- Population management is becoming an increasingly important tool for the management of type 2 diabetes. Requirements for success includes disease registries, electronic health records, evidence-based treatment protocols and decision support tools, self-management support, team-based diabetes care, and a focus on patients at risk for poorer outcomes

CONCLUSION

While the science of both nonpharmacologic and medications to treat type 2 diabetes and its complications has exploded, the technologies to assist in improving glycemic control are being developed at a similarly impressive pace. Importantly, all of these advances are resulting in better clinical outcomes. The challenge now is to translate this wealth of new information to the millions of people who can benefit, ideally in a cost-effective manner.

INTRODUCTION

Allogeneic whole organ pancreas and isolated islet transplantation are established approaches to β cell replacement therapy for the treatment of insulin-dependent forms of diabetes that restore normoglycemia with minimal glucose variability, may reverse microvascular complications, and protect against life-threatening metabolic disturbances.[1-6] Because β cell replacement therapy currently requires a deceased pancreas donor (for pancreas transplant or islet isolation) and immunosuppression, transplantation is limited to selected high-risk patients with diabetes, usually with recurrent severe hypoglycemia and hypoglycemia unawareness or with renal failure requiring kidney transplantation.[2,7-9] Most pancreas and islet transplant recipients have type 1 diabetes mellitus (T1DM), but approximately 10% to 15% of simultaneous pancreas-kidney (SPK) transplants and an increasing number of pancreas-after-kidney transplants are performed in patients with type 2 diabetes mellitus (T2DM), and rarely pancreas or islet transplantation is performed for other forms of diabetes, including post-pancreatectomy or cystic fibrosis–related diabetes.[2,10] Development of new renewable cell sources and advances in immunoprotection of islets are promising avenues to bring islet replacement therapy to a larger group of patients.[7,8,10]

Unlike pancreas and allogeneic islet transplantation, *auto*logous islet transplantation is performed to preserve a patient's own islets when performing total pancreatectomy to treat exocrine pancreatic disease (usually chronic or recurrent acute pancreatitis).[11] Most patients who undergo this procedure do not have diabetes before pancreatectomy and autoislet transplantation. Immunosuppression is not required because there is no risk for alloimmune rejection, or recurrent autoimmunity. In addition to being an important therapy to minimize or prevent diabetes in patients who require total pancreatectomy, autoislet transplantation has served as a unique model for islet transplantation in the absence of immunity and provided first proof-of-concept to support work in islet allotransplantation.[12]

KEY POINTS

- Allogeneic pancreas and islet transplantation can restore endogenous β cell function for a select group of patients with diabetes mellitus (most often type 1 diabetes) complicated by renal failure or recurrent severe hypoglycemia. Autologous islet transplantation is performed in patients without diabetes undergoing total pancreatectomy to treat chronic pancreatitis; because patients receive their own islets, no immunosuppression is needed for autotransplantation.

Historical Perspective

The first human pancreas transplant was performed by Dr. Kelly and Dr. Lillehei in 1966 at the University of Minnesota, as a duct-ligated segmental pancreas graft along with a simultaneous kidney transplant.[13,14] This first procedure resulted in only transient insulin production and was followed shortly thereafter by a second pancreas transplant with only a short period (<2 months) of insulin independence.[14] Thereafter, Dr. Najarian and Dr. Sutherland led the pancreas transplant program and reported a greater number of procedures over the following two decades.[1] Their efforts and those of others led to advances in the technical procedures, including drainage of pancreatic duct secretions, development of improved immunosuppression, cyclosporine, and T-cell depleting induction (antilymphocyte globulin), which led to more robust success. Beginning in the 1980s, utilization of pancreas transplantation as a treatment for T1DM gained greater attention and traction.[1] As of 2019, more than 33,000 pancreas transplant procedures had been performed in the United States, and more than 53,000 worldwide, the majority of these being SPK transplant.[2,15]

Around the same time as whole-organ pancreas transplant was introduced in clinical practice, researchers were exploring the concept of isolating and transplanting pancreatic islets. Isolated islets were shown to be successful in reversing diabetes in rodent models in work by Paul Lacy at Washington University and Clyde Barker at the University of Pennsylvania in the early 1970s.[16,17] Based on experience with large animal models of islet transplantation in the 1970s, the intraportal site was selected as the most promising site for islet infusion.[18] Subsequently, the first isolated human islet transplants were performed in the 1970s, with the first islet allograft to treat type 1 diabetes performed in 1974 and the first islet autograft to treat surgical diabetes (pancreatectomy) in 1977.[19-22] Initial allogeneic islet transplants for T1DM were unsuccessful, largely because of inadequate immunosuppression, β cell toxicity of glucocorticoids, and use of inadequate β cell mass. In contrast, the first patient to receive a total pancreatectomy with autoislet transplant was insulin-independent for 2 years, thus providing proof of concept for the procedure of islet isolation and transplantation.[22]

Subsequent efforts in islet transplant focused on both developing the procedures for isolating viable islets more effectively and tailoring transplant immunosuppression protocols to enhance alloislet graft survival. The semiautomated method of islet isolation was introduced by Camillo Ricordi in 1988, and shortly thereafter, in 1990, Dr. Lacy and Dr. Scharp reported the first case of insulin independence for 13 months in an islet allograft recipient.[23,24] Prolonged insulin independence remained rare (~10% of islet allograft cases) until 2000, when James Shapiro and colleagues introduced the Edmonton protocol, which restored insulin independence in seven of seven recipients by increasing the transplanted islet mass (β cell mass) by using at least two pancreas donors for each recipient and removing corticosteroids from the transplant immunosuppression regimen.[25] Since that time, modification of induction immunosuppression to include T-cell–depleting agents and tumor necrosis factor (TNF)-α inhibitors has allowed for increased ability to restore insulin independence with a single islet graft and better longevity of insulin independence.[4,26]

Access to islet transplantation varies by geographical region. In many areas of Europe, Canada, and Australia this procedure is considered standard of care, whereas in the United States isolated islets can only be administered under an Investigational New Drug protocol. The National Institutes of Health–-sponsored multicenter Clinical Islet Transplant (CIT) consortium was established to conduct multicenter trials to support future US Food and Drug Administration (FDA) licensure of islets as a clinical therapy for selected patients with type 1 diabetes. The resulting CIT-07 trial, published in 2016, demonstrated efficacy of islet allotransplantation to eliminate severe hypoglycemia and reduce glucose variability, while meeting glycated hemoglobin (HbA1c) targets for near-normal glycemic control (≤6.5%), in patients with longstanding type 1 diabetes and hypoglycemic unawareness.[3] The subsequent CIT-06 trial, published in 2020, demonstrated similar efficacy in patients who had a previous kidney transplant and also, importantly, the safety of preserved renal allograft function.[27] In the modern era, from 2000 to 2015, more than 1000 islet allotransplant recipients and more than 2100 islet transplant procedures were reported to the Collaborative Islet Transplant Registry (CITR).[28]

Autoislet transplant is often discussed separately from the alloislet transplant because the patient population, indication for transplant, and postoperative management (no immunosuppression) are different.[29,30] Since the first successful autoislet transplant procedure was reported in 1977, total pancreatectomy with autoislet transplantation slowly gained traction as a therapy for chronic pancreatitis. Early reports in the 1990s established the insulin secretory capacity of autoislets and ability to achieve insulin independence when sufficient numbers of islets could be isolated from the diseased and fibrotic pancreas, and, in the absence of autoimmunity, early autoislets exhibited better durability than alloislet transplants.[31,32] As more data emerged to support the success of total pancreatectomy with autoislet transplant to relieve the unrelenting pain of pancreatitis and restore quality of life, acceptance of this procedure as a treatment for pancreatitis among pancreatologists grew, and the number of centers performing the procedure increased in the United States over the past 10 to 15 years.[11,33,34] Although the number of autoislet transplants performed is not as systematically tracked as pancreas and islet allotransplants, based on data from the CITR and the published literature it is likely at least 1500 autoislet transplants have been performed worldwide with high success rates, with most occurring in the United States.[34]

KEY POINTS

- Pancreas transplantation was first performed in 1966; more than 53,000 procedures have been performed worldwide, with the majority performed as a simultaneous pancreas-kidney transplant. Islet transplants were first performed in the 1970s, with proof of concept for diabetes remission established with the first autoislet recipient in 1977. Refinements in immunosuppression and use of multiple pancreas donors have improved islet allotransplant outcomes in the modern era.

PANCREAS TRANSPLANTATION

Patient Selection for Pancreas Transplantation

Pancreas transplantation is considered for restoration of normoglycemia in patients with insulin-dependent diabetes who have renal failure requiring kidney transplantation or who suffer acute metabolic complications of diabetes, particularly recurrent severe hypoglycemia. The majority of transplant recipients have type 1 diabetes. However, an increasing number of SPK transplant procedures have been performed in those with insulin-dependent T2DM, now comprising approximately 15% of those on the waitlist for pancreas transplantation in the United States.[2] In the United States, the Pancreas Allocation System introduced by the United Network of Organ Sharing in 2014 established a national policy for pancreas allocation that included restricting SPK for T2DM to those with low C-peptide levels (≤2 ng/mL fasting). If C-peptide was greater than 2 ng/mL, the recipient needed to be less than a maximum allowed body mass index (BMI; initially 28 kg/m^2 and later 30 kg/m^2). However, in 2018 to 2019 these qualifying criteria were removed, and selection of candidates with T2DM is now at the discretion of the local transplant center.[35] Rarely, pancreas transplant has been performed for other forms of diabetes. In patients who have a total pancreatectomy alone or with a failed autoislet transplant, pancreas transplant has been performed in those with severe glycemic lability or recurrent severe hypoglycemia and can have a secondary benefit of reversing exocrine insufficiency.[36,37] Patients with insulin-dependent cystic fibrosis–related diabetes who require a liver transplant or lung transplant and thus are already treated with immunosuppression may also be candidates for pancreas transplant.[38]

Surgical Approaches to Pancreas Transplantation

Most pancreas transplants are performed in patients with T1DM who also require kidney transplantation. Over 80% of pancreas transplants are performed as an SPK, and approximately 10% as pancreas-after-kidney transplants.[2] The SPK approach allows for the possibility of restoring normoglycemia and insulin independence with a single surgical procedure.[39] Because these patients already require major surgery and immunosuppression for kidney transplant, and because the addition of a pancreas graft can improve patient and kidney graft survival, the risk-benefit ratio is easy to justify. Although it requires a second transplant surgery, pancreas-after-kidney is considered for patients experiencing poor or unstable glycemic control with prior living related donor kidney transplant, deceased donor kidney without pancreas transplant, or a prior simultaneous pancreas and kidney but with a failed pancreas graft. Only approximately 10% of pancreas transplants are pancreas transplants alone, without simultaneous kidney (or other organ) transplants, usually used for severe glycemic lability and hypoglycemia unawareness and/or recurrent severe hypoglycemia warranting risks of major surgery and immunosuppression.[2,40]

Nearly all pancreata transplanted are procured from deceased donors. Transplant of a segmental pancreas graft (hemipancreas) from a living donor is feasible and was performed in the past, most often for living donor SPK transplant, less often as a solitary hemipancreas for pancreas-after-kidney or hemipancreas transplant alone.[41] Between 1979 and 2008, 155 living donor pancreas transplants were reported to the International Pancreas Transplant Registry, with the vast majority (92%) performed in the United States.[41] An historically important observation came from a twin study in which a diabetic twin received a hemipancreas from her nondiabetic twin. Because they were identical twins, no immunosuppressive drugs were given to the recipient. However, soon after the transplant the recipient again became hyperglycemic. Biopsy of the donated hemipancreas did not show signs of rejection but did demonstrate necrotic β cells. This indicated that the recipient's autoimmune response was activated by her identical twin's β cells, illustrating the autoimmune nature of T1DM.[42] Moreover, anti–T-cell immunosuppression proved highly effective at abrogating β cell autoimmunity. As a living related donor often shares human leukocyte antigens with the recipient, in the early era of pancreas transplantation a living related donor offered an immunologic benefit with lower risk for alloimmune pancreas rejection. However, with current immunosuppression, use of a deceased donor pancreas offers similar pancreas graft survival, and thus it is difficult to justify the risk of hemipancreatectomy for a living donor. Hemipancreatectomy for the donor is associated with surgical risks including splenectomy (4%–20%), pancreatic fluid collection (<5%–11%), and pancreatitis (4%) and metabolic risks associated with reduced pancreatic islet mass.[41,43] Metabolic study of living pancreas donors showed increased fasting glucose and 25% with impaired glucose tolerance at 1 year after hemipancreatectomy, reduced insulin secretion to intravenous glucose or arginine, reduced glucagon secretory response to arginine but preserved response to hypoglycemia, and long-term increased risk for diabetes mellitus, especially with higher BMI.[44-47] Despite refined protocols restricting pancreas donors to nonobese individuals with adequate insulin secretory responses lacking insulin resistance, long-term risk for diabetes mellitus remained relatively high, with one in every four patients developing diabetes by an average of 7 to 9 years after hemipancreatectomy, with one out of 10 on insulin treatment.[43,48]

For current pancreas transplants, the entire pancreas and a small segment of duodenum (for anastomoses to bowel or bladder for drainage of exocrine secretion) is procured from an appropriate ABO-compatible deceased donor without history of diabetes mellitus. Historically, most donor pancreases were procured from "ideal" nonobese, brain dead donors of relatively younger age. Donor selection protocols have evolved over time to accept organs from deceased donors previously considered nonideal, including donors after circulatory death or donors with higher BMI (>30 kg/m^2), thus expanding the donor pool.[49] Emerging data suggest no detrimental outcomes in 1-year graft survival when SPK or pancreas transplant alone were performed with organs from donors after cardiac death versus brain death.[50] In experienced transplant centers with high transplant volumes, more aggressive donor selection protocols do not appear to adversely impact outcomes.[51]

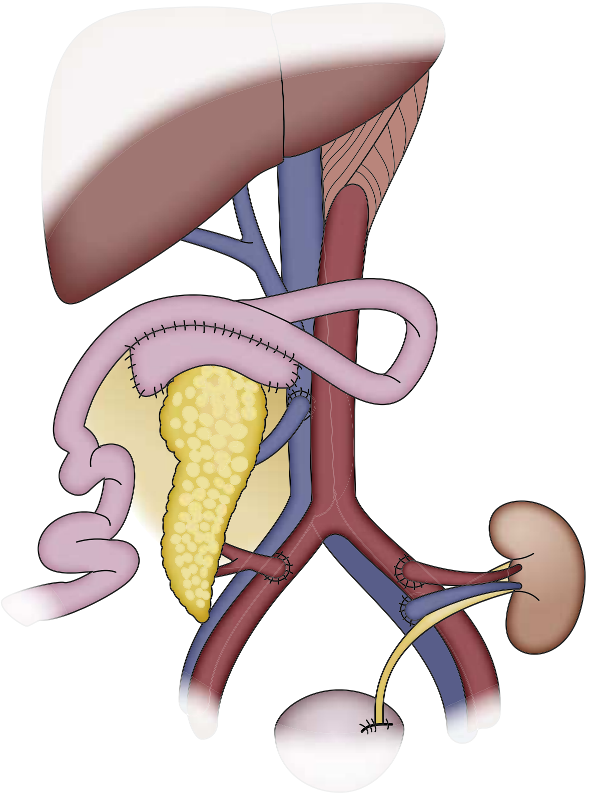

Fig. 41.1 Simultaneous Pancreas-Kidney Transplant. The majority of procedures involve enteric drainage of exocrine secretions from the pancreaticoduodenal graft, arterial reconstruction with a Y-graft of donor ileac arteries anastomosed to the recipient ileac artery, and venous anastomosis of the graft portal vein to the common ileac vein or inferior vena cava (systemic venous drainage) or less commonly the superior mesenteric vein (portal venous drainage). (Reproduced with permission from Larsen JL. Pancreas transplantation: indications and consequences. *Endocr Rev.* 2004;25:919–946.)

The procured pancreas is transplanted in the right ileac fossa of the transplant recipient, with a similar approach for SPK, pancreas-after-kidney, or pancreas transplant alone (Fig. 41.1).[52] Systemic venous drainage is most often established by anastomosing the donor pancreatic vein to the recipient ileac vein or inferior vena cava.[53] Thus, in contrast to the physiology of the native pancreas, in which insulin is secreted into the hepatic portal circulation, after pancreas transplantation insulin from the transplanted pancreas is secreted into the systemic circulation, resulting in mild peripheral hyperinsulinemia.[53-55] An alternate but less common approach is to anastomose the donor portal vein to the recipient superior mesenteric vein to achieve portal venous drainage, but this approach has a greater technical burden and unclear long-term metabolic benefit over systemic drainage for the recipient.[56,57] For management of the exocrine secretions of the pancreas, the donor duodenum can be anastomosed to the bladder (bladder drainage) or anastomosed to the recipient jejunum (enteric drainage) by creating a roux loop from recipient jejunum or by a side-by-side anastomosis to the recipient jejunum.[53,55] Bladder drainage offered the historical advantage of closer monitoring for rejection via measurement of urinary lipase and amylase levels. However, bladder drainage was also complicated

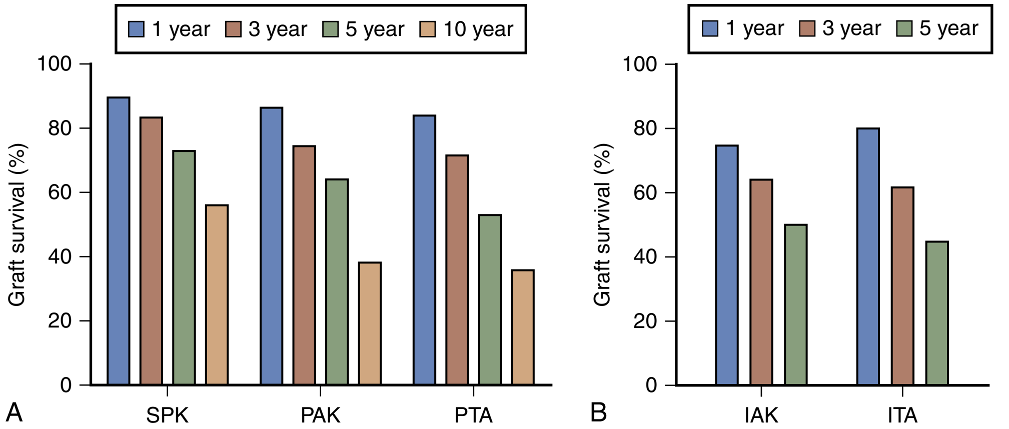

Fig. 41.2 **A,** Pancreas and **B,** islet graft survival defined by registry definitions of insulin independence after pancreas transplant and C-peptide ≥0.3 ng/mL for islet transplant. IAK, islet-after-kidney, ITA, islet transplant alone, PAK, pancreas-after-kidney, PTA, pancreas transplant alone, SPK, simultaneous pancreas-kidney. (Data from Collaborative Islet Transplant Registry: 10th Annual Report. https://citregistry.org/system/files/10th_AR.pdf. Accessed 2/20/2020.)

by metabolic acidosis, hematuria, recurrent urinary tract infections, urethritis, and urethral strictures, making this approach difficult to tolerate for many transplant recipients, and a surgical conversion to enteric drainage was required in 9% to 19% of patients.[1] With improved immunosuppression, and now procedures for radiologic-guided pancreas biopsies, the disadvantages of bladder drainage now outweigh the benefit for most pancreas transplant recipients, and enteric drainage is more often favored (used in more than 90% of recent cases).

Patient and Graft Survival After Pancreas Transplant

Patient survival after pancreas transplant is approximately 97% at 1 year and 65% to 72% at 10 years for SPK, pancreas-after-kidney, or pancreas transplant alone.[58] Pancreas graft survival (as traditionally defined by insulin independence) is highest with a SPK transplant, at 90% at 1 year and 56% at 10 years; in pancreas-after-kidney or pancreas transplant alone, pancreas graft survival is around 84% to 87% at 1 year and decreases to 36% to 38% at 10 years (Fig. 41.2).[58,59] Survival of the pancreas graft depends on technical and immunologic factors. Early pancreas graft loss may occur secondary to technical complications (most commonly graft thrombosis), pancreatitis, or immunologic rejection, while late pancreas allograft loss is often immunologically mediated, because of alloimmune rejection or autoimmune recurrence.[58,60] Several studies have shown superior pancreas graft survival when procedures are performed at high-volume pancreas transplant centers (defined by >11–14 procedures per year), even despite a tendency of higher volume centers to accept higher risk organs for transplant.[61-63]

Receiving a pancreas transplant with a kidney transplant appears to convey a survival benefit when compared with patients with T1DM who undergo renal transplant alone. In a 30-year follow-up cohort in The Netherlands, SPK transplant reduced mortality by 44% at 10 years (hazard ratio 0.56) and by 31% at 20 years compared with deceased or living donor kidney transplant alone, and these benefits were particularly strengthened by having a functioning pancreas graft.[39] Additional studies from the United States and the United Kingdom similarly found a benefit of SPK and/or pancreas-after-kidney transplant on patient survival, as well as significantly better survival of kidney graft, likely related to the lack of chronic hyperglycemia exposure to the newly transplanted kidney.[64-66]

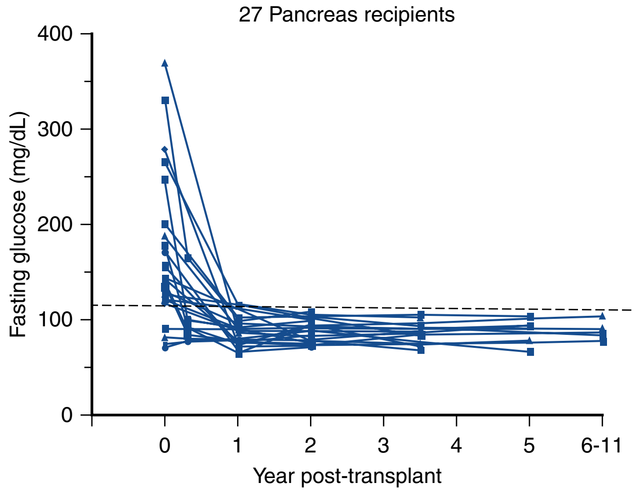

Fig. 41.3 Fasting blood glucose in 27 insulin-independent pancreas transplant recipients demonstrating restoration of normoglycemia for >5 years posttransplant.

Metabolic Outcomes

Successful pancreas transplantation almost invariably results in fasting blood glucose levels that are below 110 mg/dL (Fig. 41.3), and HbA1c levels are well below those achieved by intensive insulin treatment reported in the DCCT trial (Fig. 41.4). Insulin and C-peptide secretion are usually assessed during oral and intravenous glucose tolerance tests. Insulin levels in the basal and glucose-stimulated state after pancreas transplantation are slightly elevated (Fig. 41.5) because the venous return from the transplanted pancreas is emptied into a vein (usually the iliac vein) that leads directly to the inferior vena cava.[53-55] The latter situation is very different from the blood return from the native pancreas, which delivers insulin via the portal vein directly into the liver, where insulin is metabolized at least by 50% in a single passage. The postoperative complication of hypoglycemia rarely occurs after pancreas transplantation, probably because the transplanted pancreas, unlike the native pancreas in people with type 1 diabetes, secretes glucagon normally in response to hypoglycemia, and consequently restores hepatic glucose production during hypoglycemia that is

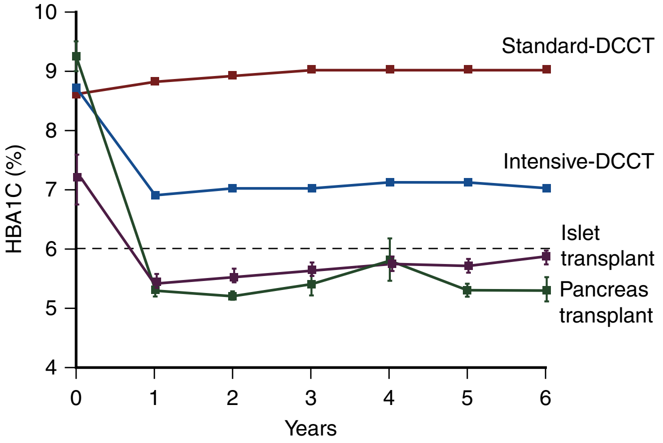

Fig. 41.4 Glycated hemoglobin (*HbA1c*) levels normalize after pancreas (authors' data) and islet transplant (updated data from Rickels MR, Liu C, Shlansky-Goldberg RD, et al. Improvement in β-cell secretory capacity after human islet transplantation according to the CIT07 protocol. *Diabetes*. 2013;62:2890–2897), contrasted with medical insulin therapy in the Diabetes Control and Complications Trial (DCCT).

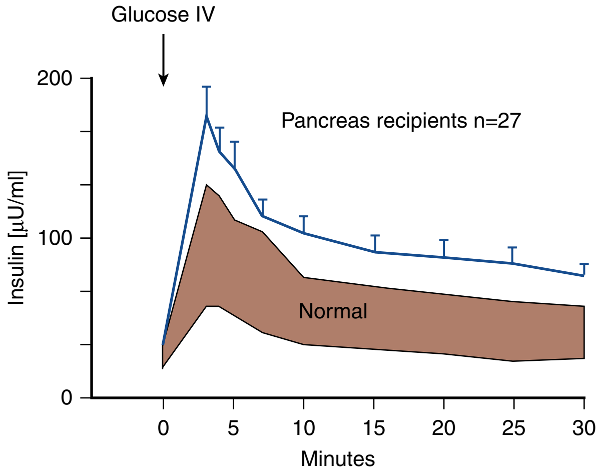

Fig. 41.5 Pancreas transplant recipients exhibit normal restoration of first phase insulin secretion in response to an intravenous glucose bolus, with higher insulin levels versus controls because of the systemic drainage of the transplanted pancreas. *IV,* Intravenous.

necessary to prevent or correct low blood glucose (Fig. 41.6).[67-69] This is of interest, because the intrapelvic transplanted pancreas is unlikely to receive meaningful intracranial sympathetic or parasympathetic nerve inputs, which have been shown to contribute to glucagon release during hypoglycemia in normal, nontransplanted subjects. This speaks to the efficiency of the transplanted pancreas alone, independent of the central nervous system as a provider of glucagon secretion during hypoglycemia.

KEY POINTS

- Pancreas transplantation is performed for type 1 (85%) and type 2 (15%) diabetes. Pancreas graft survival is 85% to 90% at 1 year and 36% to 87% at 10 years, with the highest pancreas survival in simultaneous pancreas-kidney transplant. Because the venous drainage of the pancreas graft is usually systemic, insulin levels are mildly elevated after successful pancreas transplant, but with normal fasting glucose and HbA1c and restoration of glucagon responses to hypoglycemia.

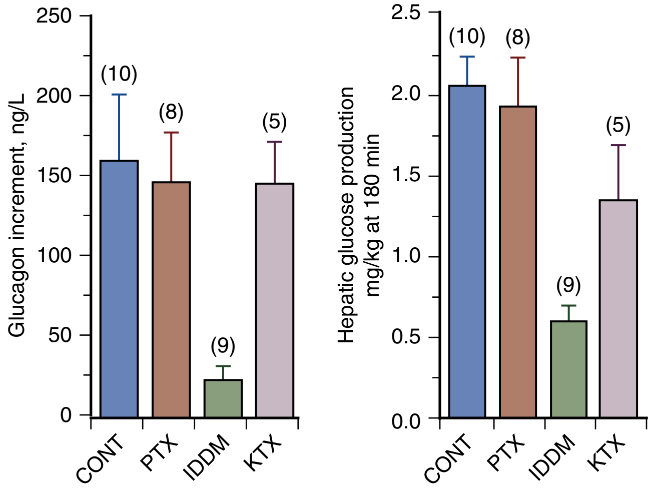

Fig. 41.6 Glucagon and hepatic glucose production during hypoglycemic clamp studies are normalized in pancreas transplant (*PTX*) recipients when compared with controls (*CONT*). In contrast, type 1 diabetes mellitus (T1DM) without transplant show significantly impaired glucagon and hepatic glucose output in response to hypoglycemia. Nondiabetes kidney transplant (*KTX*) are displayed as a transplant control group. *IDDM*, insulin-dependent diabetes mellitus or T1DM. (From Barrou Z, Seaquist ER, Robertson RP. Pancreas transplantation in diabetic humans normalizes hepatic glucose production during hypoglycemia. *Diabetes*. 1994;43(5):661–666.)

ALLOGENEIC ISLET (ALLOISLET) TRANSPLANTATION

Patient Selection for Alloislet Transplantation

The appeal of an islet transplant alone compared with pancreas transplantation alone is that the transplant procedure is relatively minor compared with the major surgery required for a whole pancreas, with very low risk for procedural complications.[10] Similar to pancreas transplants, islet allografts can be performed as islet transplant alone, islet-after-kidney transplant, or simultaneous islet-kidney transplant.[28,70,71] However, in contrast to pancreas transplants, the vast majority of procedures performed to date are islet transplant alone, followed by islet-after-kidney, and seldom simultaneous islet-kidney. In the CITR, which tracks all islet allografts performed in the United States and the many of those performed worldwide, 81% of reported transplants were islet transplant alone, 17% islet-after-kidney, and only 2% simultaneous islet-kidney.[28]

Nearly all islet allotransplants to date have been performed for patients with T1DM, most often for treatment of excessive glycemic lability, hypoglycemia unawareness, and severe hypoglycemia despite optimal medical therapy, or, in the case of islet-after-kidney, inability to maintain adequate glycemic control using exogenous insulin.[3,71-76] In the phase 3 multicenter CIT-07 trial, which was designed to collect clinical data to support licensure of islets as a cellular therapy in the United States, adult patients with C-peptide–negative type 1 diabetes of 5 years or more duration were considered candidates for islet transplant alone if they had impaired awareness of hypoglycemia (Clarke score ≥4) or marked glycemic lability, and a history of severe hypoglycemic episodes in the prior year despite optimal medical therapy.[3] Similar criteria have been used to determine candidacy across other studies and centers, including in the European-based phase 3 multicenter, two-arm, open-label TRIMECO study comparing islet transplant alone to insulin therapy.[70,72,77] For these patients, the risk-benefit ratio of taking immunosuppression is considered reasonable in comparison to the high risks for recurrent life-threatening severe hypoglycemia with medical management with insulin. For patients with a prior history of kidney transplant and T1DM, islet-after-kidney transplant is considered, including in the phase 3 multicenter CIT-06 trial, if patients had impaired hypoglycemia awareness and experienced severe hypoglycemia (similar to islet transplant alone) or if unable to achieve a HbA1c level less than 7.5% despite optimal medical management with insulin therapy.[27] For islet-after-kidney, the relative risks associated with islet allotransplant are less, as the patient is already receiving immunosuppression, and the surgical procedure is minor. The theoretical risk that an islet allotransplant could create an antigenic stimulus that may increase risk for kidney rejection has not been observed in the course of phase 3 investigation.[27] Less commonly, islet allotransplantation (as islet transplant alone) has been performed in patients with type 1 diabetes and early microvascular complications, with the goal of halting progression of microvascular disease.[6,78,79]

Under most protocols, patients with type 1 diabetes who also have high insulin needs (>1 U/kg/day) or high BMI (>30 kg/m^2) are ineligible for islet allotransplantation, as the transplanted islet mass may be insufficient to provide clinical benefit in the setting of insulin resistance.[3,27] In part for this reason, unlike whole organ pancreas transplantation, islet transplant is not currently considered for patients with T2DM. Only rarely has islet transplantation been performed for patients with other types of diabetes mellitus. There are a few case reports from Canada and Europe of islet allotransplantation performed for cystic fibrosis–related diabetes in patients also receiving lung and/or liver transplants or for postpancreatectomy diabetes mellitus.[80-84]

The number of patients with T1DM that can receive islet allotransplants is currently limited by both the risks of immunosuppression and the limited supply of islets. However, the approach of islet transplantation carries the potential to develop renewable sources of cells (discussed later) and for engineering of islets or the transplant site to reduce the need for immunosuppression in the future.

Surgical Approaches to Alloislet Transplantation

Pancreatic islets for transplant are procured from an ABO blood type–compatible deceased donor pancreas. Selection of deceased donors for islet transplantation includes consideration of both organ viability and the likelihood that sufficient numbers of islets will be obtained for transplant. Islet allotransplant is conventionally performed only if greater than 4000 to 5000 islet equivalents per kilogram recipient body weight (IEQ/kg) are obtained from the isolation procedure, as the islet mass transplanted needs to be sufficient to justify the risk of administering immunosuppression, particularly in islet transplant alone.[3,85] The majority of pancreases are obtained from brain dead donors owing to a desire to avoid pancreatic ischemia associated with cardiac death, although some islet transplants from cardiac death donors have been reported.[86,87] In contrast to pancreas transplant, in which high-BMI donors are avoided, in islet transplantation donors with high BMI or high body surface area are desirable, as these organs also yield a greater islet mass.[88] Thus, islet transplants provide opportunity to use donor organs that would otherwise have been discarded for whole-organ pancreas transplant. Islet allotransplant can also use pancreases from older donors that are not accepted for whole-organ pancreas transplant. However, when available, younger donors (age <45 years) provide more functional and viable islets.[89,90]

Once the donor pancreas is procured, the pancreas must be transported to the islet isolation facility. Islet processing is often performed locally (at the same institution performing the transplant), but some countries have developed regional islet isolation networks where islets are isolated at designated centers and then distributed to the transplanting facility to improve patient accessibility to islet transplantation, with similar metabolic outcomes for the recipient.[91-95] A cold ischemia time of less than 8 hours (maximum 12 hours) is necessary to optimize viability of the transplanted islets.[96,97] Allogeneic islets are considered an investigational biologic therapy in the United States, and thus islet manufacturing process are regulated under FDA current Good Manufacturing Practices.

Islet isolation is performed by enzymatic and mechanical digestion of the pancreas. In the islet lab, the pancreatic duct is cannulated, and a collagenase and neutral protease enzyme cocktail is infused intraductally under pressure.[96,98,99] Following completion of enzymatic distention, the pancreas is mechanically disrupted by use of the semiautomated Ricordi method, and the islets are further purified by density centrifugation, targeting a total tissue volume of less than 7.5 to 10 mL.[96,100] Isolated islets are maintained in a culture media for 36 to 72 hours while the transplant recipient begins induction immunosuppression. This culture period may also reduce immunogenicity of the graft by decreasing class I human leukocyte antigen (HLA) expression, passenger leukocytes, and islet production of chemokines and tissue factor before infusion.[101-105]

For the transplant procedure, the islets are infused intraportally into the liver either through direct access of the portal vein via a transhepatic percutaneous approach with interventional radiology guidance (Fig. 41.7) or via infusion in a mesenteric or omental vein accessed by minilaparotomy.[97,106-108] The expression of tissue factor on the surface of the islets to the portal blood triggers an instant blood-mediated inflammatory reaction. This inflammatory reaction can cause a partial loss of transplanted islets, as suggested by preclinical studies and biomarkers in autoislet recipients, and causes risk for thrombosis around the islet graft.[109-113] Portal branch vein thrombosis has been reported in 3% to 4% of transplant recipients historically, but less frequently in the more recent era, and typically resolves with anticoagulation therapy.[114] Heparin is administered with the islets and subsequently by intravenous infusion to minimize this risk for portal vein thrombosis[114] and transitioned to subcutaneous administration for at least the first week posttransplant to prevent microthrombi from affecting islet revascularization. Unlike whole-organ pancreas transplants, islets are devascularized at the time of transplantation and infused into a relatively hypoxic environment, and will require several weeks to engraft.[115] Thus, islet allotransplant recipients are placed back on insulin therapy after the procedure, and insulin is weaned as tolerated over the next few months as islets engraft and become more functional.[3,27]

Patient and Graft Survival After Alloislet Transplant

Patient survival after alloislet transplant is high. Of 1086 alloislet recipients in the CITR, the mortality rate was 3% over a mean follow-up duration of 4.2 years (± 3.5 years standard deviation [SD]), 57% of which occurred in transplant recipients transplanted in the earliest registry era (1999–2002). Over half of deaths occurred in simultaneous islet-kidney transplant recipients, even though this procedure comprised only 2% of all islet transplants. Islet transplant alone recipients had a 98% rate of survival at 5 years posttransplant. This compares to a reported mortality rate of 4% over a mean follow-up duration of 2.7 years (± 2.8 years SD) among individuals with T1DM referred for islet transplantation who are either found to be unsuitable for transplant or remained active on the waiting list.[116]

Islet graft survival is most commonly defined by detectable C-peptide production. Insulin independence and resolution of severe hypoglycemia while meeting HbA1c targets are common endpoints reported in clinical trials of islet transplantation.[3] Data from the CITR suggest improvements in insulin independence and islet function as greater experience and refinement of islet transplant protocols have evolved. Recipients of islet transplants performed in the more recent

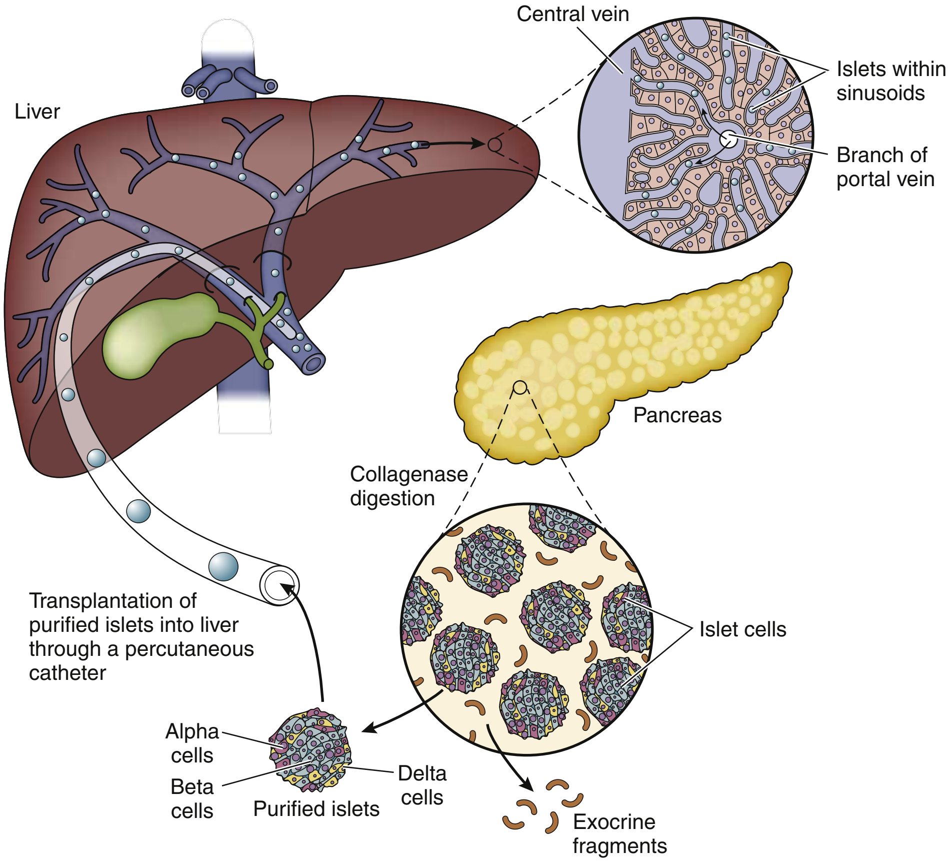

Fig. 41.7 Allogeneic Islet Transplantation. The procedure involves procurement of a deceased donor pancreas for collagenase digestion and centrifuge purification in a current good manufacturing practice islet isolation facility. The final islet product may be cultured for up to 72 hours before intraportal delivery to the main portal vein using percutaneous, transhepatic access, as shown here, or via mesenteric vein access achieved by minilaparotomy. era were insulin-independent in 66% of cases at 1 year, 55% at 2 years, and 44% at 3 years. Nearly 90% were C-peptide–positive through 3 years.[75] When current standard immunosuppression regimens was given, including T-cell–depleting induction therapy and TNF-α inhibition, the 5-year insulin independence rate was 50%, similar to pancreas transplant alone.[4] Recipient characteristics may also affect outcomes, with age 35 years or over associated with more favorable outcomes.[28] More than one pancreas donor may be required to achieve sufficient islet mass for insulin independence. CIT-07, CIT-06, and the CITR data indicate that 28% to 46% of islet transplant alone recipients received a single islet graft, while others received two or more infusions to reach reported metabolic outcomes.[3,27,28,75] However, high rates of prolonged insulin independence can be achieved with a single pancreas donor providing greater than 6000 IEQ/kg under appropriate immunosuppression.[26,117] Achievement of insulin independence is associated with significantly longer islet graft survival,[75] suggesting a long-term benefit to targeting initially high islet engraftment.

Because islet transplant alone is primarily performed to treat type 1 diabetes complicated by hypoglycemia unawareness and recurrent severe hypoglycemic episodes, the primary therapeutic goal of islet transplantation is often to resolve severe hypoglycemia, regardless of whether partial exogenous insulin supplementation is still needed. In the phase 3 CIT-07 trial, the primary endpoint of islet transplant alone was complete resolution of hypoglycemia (days 28–365 posttransplant) with HbA1c less than 7%, an endpoint that was determined in consultation with the FDA. At 1 year, 87.5% met the primary endpoint, and at 2 years the median HbA1c was maintained at 5.6%.[3] Secondary analyses from this trial as well as the phase 3 CIT-06 trial further show a benefit to health-related quality of life, particularly reduced diabetes distress scores, reduced fear of hypoglycemia, and improved visual analog quality of life reported on the EuroQol-5D.[27,118]

Metabolic Outcomes

Successful alloislet transplantation rivals pancreas transplantation in terms of establishing levels of fasting glucose and HbA1c in the normal or nearly normal ranges (Figs. 41.8 and 41.4). Unlike pancreas transplantation, where systemic venous drainage bypasses first-pass hepatic insulin extraction and results in hyperinsulinemia, the intraportal delivery of transplanted islets for intrahepatic engraftment results in normal hepatic insulin extraction,[119] and fasting insulin levels are consequently normal (Fig. 41.9).[120] Like pancreas transplantation, first-phase insulin secretion follows normal secretory dynamics; however, peak insulin secretory responses are often lower than in controls or recipients of whole pancreas transplant (Fig. 41.9). This reduction in first-phase insulin secretion in response to glucose is best explained by a reduced islet β cell mass ultimately surviving engraftment.[117] Consistent with other models of reduced β cell mass, first-phase insulin secretion in response to arginine is preserved in islet transplant recipients, and the reduced functional β cell mass is most accurately measured from glucose potentiation of arginine-induced insulin secretion (GPAIS) that gives the β cell secretory capacity (Fig. 41.10). With a decreased β cell secretory capacity there is a limited insulin secretory reserve, such that

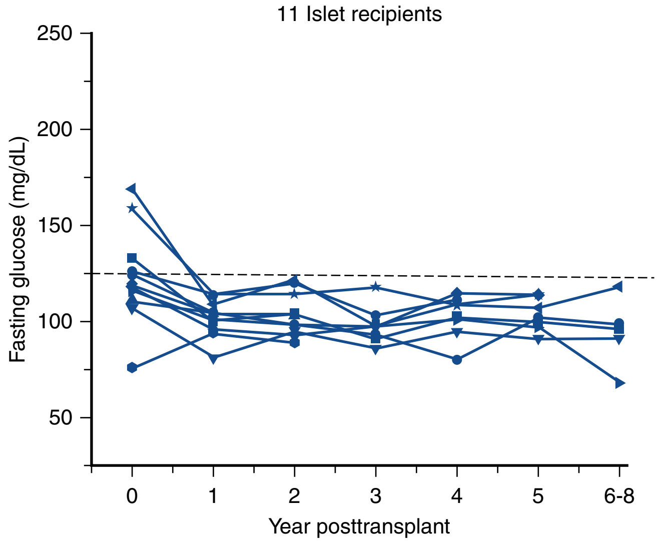

Fig. 41.8 Fasting blood glucose in 11 insulin independent islet transplant recipients demonstrating restoration of near-normoglycemia for >5 years posttransplant. (Adapted from Rickels MR, Liu C, Shlansky-Goldberg RD, et al. Improvement in β-cell secretory capacity after human islet transplantation according to the CIT07 protocol. *Diabetes*. 2013;62(8):2890–2897.)

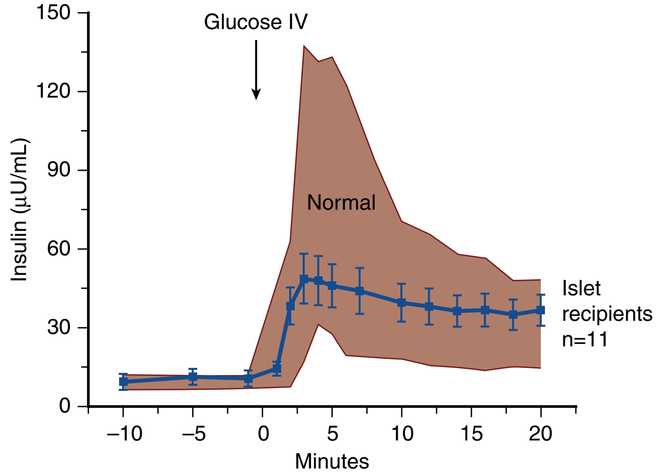

Fig. 41.9 Insulin secretion in response to an intravenous glucose bolus in islet transplant recipients shows a similar time course of first phase insulin secretion, with lower peak than control insulin values because of the reduced β cell secretory capacity of the transplanted islets surviving engraftment in the liver. *IV,* Intravenous. (Modified from data from Rickels MR, Kong SM, Fuller C, et al. Insulin sensitivity index in type 1 diabetes and following human islet transplantation: comparison of the minimal model to euglycemic clamp measures. *Am J Physiol Endocrinol Metab.* 2014;306:E1217–1224.)

even insulin-independent islet transplant recipients may require temporary periods of exogenous insulin administration during periods of intercurrent illness or pregnancy[121] that increase insulin demand. Most importantly, approximately 90% of the incidence of severe hypoglycemia and accompanying hypoglycemia unawareness is eliminated (Fig. 41.11). This is explained by a recovery of appropriate islet cell responses to hypoglycemia, with suppression of endogenous insulin secretion and partially increased glucagon secretion that, together with an improvement in adrenomedullary epinephrine secretion, restores the endogenous (primarily hepatic) glucose production response required to defend against the development of low blood glucose (Fig. 41.12).[10,122-124] This is of utmost importance, because frequent hypoglycemia and symptom unawareness is the major clinical indication for alloislet transplantation.

KEY POINTS

- In islet allotransplantation, islets are isolated from the pancreas by enzymatic and mechanical digestion and infused into the liver via the portal vein using a minor surgical procedure or interventional radiologic approach. Alloislet transplants are nearly exclusively performed for treatment of T1DM, most often for management of hypoglycemia unawareness and life-threatening episodes of severe hypoglycemia. Successful islet transplant restores sufficient insulin and glucagon secretion to maintain normal glucose homeostasis.

IMMUNOSUPPRESSIVE DRUGS

Pancreas and islet transplantation both require immunosuppression to prevent alloimmune rejection and autoimmune recurrence. In general, modern immunosuppressive therapy for either pancreas or islet transplant consists of an induction regimen that is given over a short time frame in the peritransplant period and a maintenance regimen of daily immunosuppression that is taken for as long as the transplanted organ(s) continue to function. Administration of any immunosuppression must balance the need to prevent rejection, while at the same time keeping the risks of immunosuppressive toxicities and infection as minimal as possible.[8] A unique consideration for patients with type 1 diabetes receiving a pancreas or islet transplant is that immunosuppression must also be adequate to prevent recurrence of the β cell autoimmunity of type 1 diabetes. Evidence that transplanted islet β cells are susceptible to destruction by recurrent autoimmunity was first provided by Ali Naji and colleagues using an experimental animal model.[125] As mentioned earlier, in the initial experience with living related donor pancreas transplantation, when hemipancreas transplants were performed using an identical twin or HLA-matched sibling donor in the absence of immunosuppression, recurrence of β cell autoimmunity was observed in the transplanted pancreas.[126] T-cell autoreactivity against β cell antigens has also been associated with functional graft loss in islet transplantation.[127]

Interleukin (IL)-2 receptor antagonists (daclizumab and basiliximab) or T-cell–depleting agents (antithymocyte globulin or alemtuzumab) are given for induction immunosuppression for pancreas or islet transplants, with the T-cell–depleting agents largely gaining favor in the recent era.[1,3,15,75,77] T-cell depletion is advantageous over IL-2 receptor antagonists for protection against acute cellular rejection in pancreas and islet transplants, and antithymocyte globulin may offer the additional benefit of relative expansion of the regulatory T-cell pool.[128-131] For islet transplantation specifically, TNF-α inhibition is often coadministered with T-cell depletion in the induction period to protect intraportally infused islets from the damaging effect of the instant blood-mediated inflammatory reaction.[4]

Maintenance immunosuppression in pancreas transplantation most commonly consists of the calcineurin-inhibitor tacrolimus with mycophenolate mofetil with or without a low dose of corticosteroid.[15] Sirolimus or everolimus (mTOR inhibitor) are occasionally used in place of mycophenolate mofetil. For islet transplantation, initial maintenance therapy usually includes tacrolimus with either mycophenolate mofetil or sirolimus.[3,28] Corticosteroids are generally avoided for islet transplantation because of the inherent β cell toxicity of the drug and because of the insulin resistance corticosteroids cause. Calcineurin inhibitors are a concern for their known potential

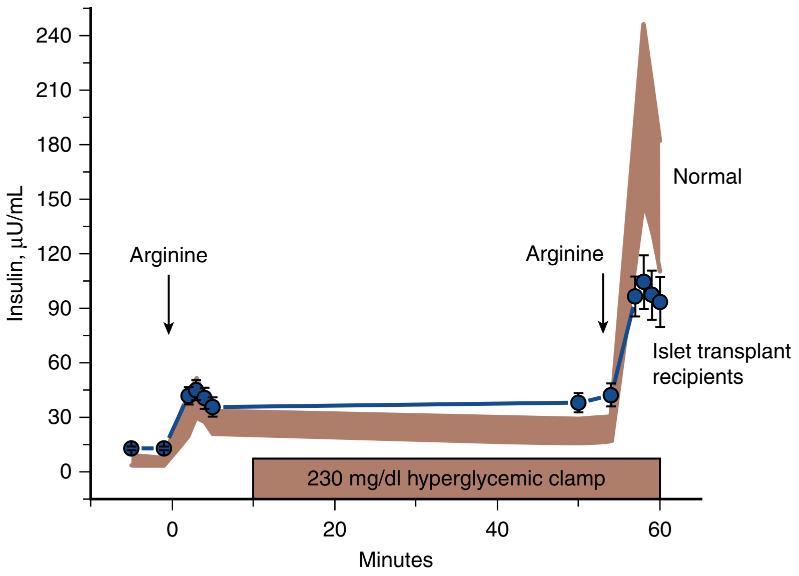

Fig. 41.10 Data demonstrating the acute insulin response to arginine and glucose-potentiated arginine stimulation in patients with type 1 diabetes mellitus after successful islet transplant in the Clinical Islet Transplant–07 study. (Reproduced with permission from Rickels MR, Liu C, Shlansky-Goldberg RD, et al. Phase 3 trial of transplantation of human islets in type 1 diabetes complicated by severe hypoglycemia. *Diabetes Care.* 2016;39:1230–1240.)

to inhibit glucose-dependent insulin secretion and potential for nephrotoxicity, but to date have been a key component of the immunosuppression cocktail to prevent rejection of a pancreas or islet graft.[132-135] Recent introduction of T-cell costimulatory blockade has offered some hope for calcineurin inhibitor–free maintenance immunosuppression. Small studies show favorable islet transplant outcomes for recipients treated with the T-cell costimulatory inhibitors efalizumab (now off the market) or belatacept in the absence of a calcineurin inhibitor.[136,137] However, in a phase 2 multicenter open-label trial in SPK transplants in which patients were randomized to conventional immunosuppression (tacrolimus plus mycophenolate mofetil) or an investigational arm of belatacept, mycophenolate mofetil, and low-dose tacrolimus with planned withdrawal of tacrolimus, more pancreas rejection events occurred in the belatacept arm, most after discontinuation of tacrolimus, and the trial was ultimately stopped early.[138]

Common side effects of immunosuppression for the transplant recipient include nausea, diarrhea, electrolyte abnormalities, oral ulcerations, hyperlipidemia, cytopenias, and increased serum creatinine. Sirolimus can be associated with painful oral ulcers, and many islet transplant recipients initially treated with sirolimus-tacrolimus require transition to a mycophenolate- tacrolimus combination for better tolerance.[139] Major concerns of immunosuppression are the risks of severe or opportunistic infection, nephrotoxicity, and cancers. The risk for skin cancer varies by geographical region and immunosuppression regimen, but overall risk for skin cancer is around 20% by 10 years after solid organ transplantation.[140] The use of calcineurin inhibitor therapy (tacrolimus, cyclosporine), alone or in combination with sirolimus, presents risk for nephrotoxicity posttransplant in patients with type 1 diabetes. In islet transplant recipients, low dose tacrolimus plus sirolimus maintenance therapy was associated with an approximately 5 mL/min/year/1.73 m^2 decline in glomerular filtration rate, but there was significant heterogeneity in between individuals.[141] Sirolimus presents an additional risk of albuminuria, present in approximately 5% of treated patients.[142] Careful selection of transplant

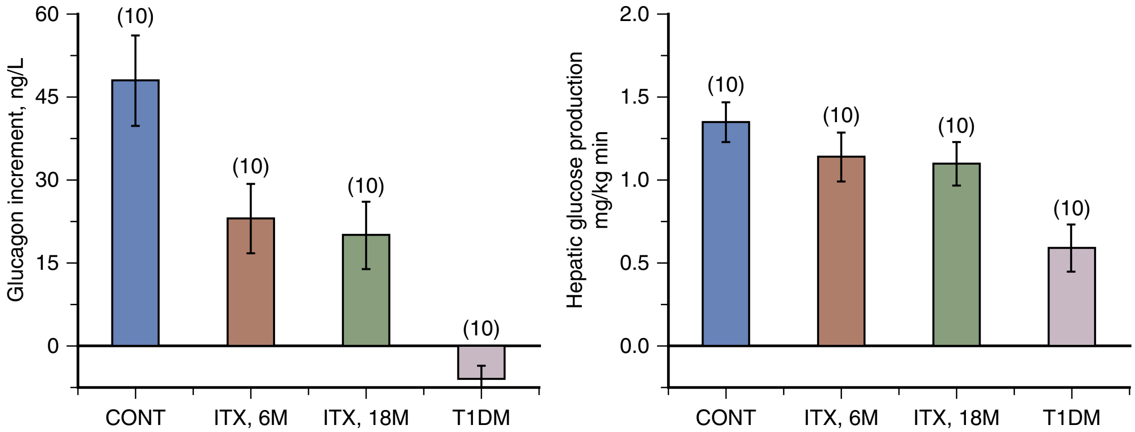

Fig. 41.12 Glucagon levels during hypoglycemic clamp studies in islet transplant (*ITX*) recipients at 6 and 18 months (*M*) posttransplant remains lower than in controls (*CONT*), but are significantly improved when compared with pretransplant levels in patients with type 1 diabetes mellitus (*T1DM*). Importantly, hepatic glucose production during hypoglycemic clamp studies is normalized in ITX recipients when compared with CONT. In contrast, T1DM patients pretransplant show significantly impaired hepatic glucose output in response to hypoglycemia. (Data from Rickels MR, Peleckis AJ, Markmann E, et al. Long-term improvement in glucose control and counterregulation by islet transplantation for type 1 diabetes. *J Clin Endocrinol Metab.* 2016;101:4421–4430.)

recipients with normal kidney function before transplant and careful monitoring of renal function and immunosuppression dosing can minimize risk for adverse renal outcomes.[143]

Epstein–Barr virus (EBV) and cytomegalovirus (CMV) are of particular concern posttransplant and are more common with T-cell–depleting induction therapies.[144-146] Valgancyclovir is commonly administered for several months posttransplant as prophylaxis against CMV. Both pancreas and islet transplant recipients are at risk for CMV, although risk is lower in islet transplant because of low tissue volume, small number of passenger donor leukocytes, and lack of lymphoid tissue in islet grafts.[145,147] Quantitative assays (polymerase chain reaction) for EBV and CMV viremia are often performed at protocol-defined intervals, even in asymptomatic patients. Posttransplant lymphoproliferative disease has been reported after pancreas transplant, but rarely after islet transplant, with transplant recipients who are EBV-seronegative at transplant at highest risk.[148,149 146] Additional antimicrobial prophylaxis after pancreas and islet transplant includes trimethoprim/sulfamethoxazole to protect against *Pneumocystis jarvii*.

Despite advances in immunosuppressive therapy, transplanted pancreas or islet grafts remain at risk for alloimmune rejection or recurrence of β cell autoimmunity. In pancreas transplant, serum amylase and lipase (or urinary amylase and lipase in the case of bladder drainage) are routinely monitored, with elevations raising concern for possible rejection.[150] In SPK transplantation, an elevated serum creatinine can be a surrogate marker for pancreas rejection, and thus rejection is often detected and treated more effectively in combined pancreas-kidney transplant than pancreas transplant alone.[1] When rejection is suspected, radiology-guided pancreas biopsy can be performed to definitively diagnose acute cellular and/or antibody-mediated rejection.[150] If diagnosed sufficiently early, before fibrosis of the pancreas graft and need for resumption of insulin therapy, acute rejection in pancreas transplant can often be treated successfully with a short course of added immunosuppression. High-dose corticosteroids and/or antithymocyte globulin are commonly used to treat acute cellular rejection, whereas antibody-mediated rejection is treated with intravenous immunoglobulin and plasmapheresis or anti-B cell therapies for refractory cases.[150] Unfortunately, in islet transplantation efficient biomarkers for rejection are largely lacking, and, because of patchy distribution of islets in the liver, biopsy diagnosis is not feasible. For islet transplants, acute rejection is often undiagnosed until the recipient presents with sudden-onset hyperglycemia, at which point islet damage is likely irreversible. Donor-specific antibodies may be present at diagnosis or preceding acute rejection.[151,152] Islet graft rescue for presumptive cases of cellular and antibody-mediated rejection have been reported.[153,154]

Recurrence of β cell autoimmunity remains a concern, and in pancreas transplantation may be distinguished from classic rejection based on biopsy features.[155] In islet transplant, recurrent autoimmunity may be suspected in the case of rapid loss of graft function in the absence of donor-specific antibodies detected in blood samples. T-cell autoreactivity has been shown to correlate with both pancreas and islet graft loss, but these cellular assays are cumbersome to perform and not clinically available.[127,156] β cell autoantibodies are less sensitive as markers of recurrent autoimmunity, but new positive antibodies or increasing antibody titers have shown some correlation with biopsy-proven type 1 diabetes recurrence in pancreas transplant recipients.[155,157] Circulating islet exosomes can delineate cell type–specific islet damage and in at least one case has provided proof of concept to distinguish specific β cell loss typical of recurrent autoimmunity from the more general islet destruction associated with classic alloimmune rejection.[158]

KEY POINTS

- Both pancreas and alloislet transplant recipients must take immunosuppressive drugs to prevent rejection and recurrence of autoimmunity (in type 1 diabetes). Immunosuppression must be carefully monitored to provide sufficient dosing to mitigate risk for pancreas or islet rejection, while minimizing drug toxicity. Minor side effects (e.g., gastrointestinal symptoms) are common, while less common but serious risks of treatment include renal insufficiency, opportunistic infections, or malignancy.

AUTOLOGOUS ISLET (AUTOISLET) TRANSPLANTATION

Patient Selection for Autoislet Transplantation

Autologous islet transplantation is most often performed for patients with recurrent acute and/or chronic pancreatitis who are undergoing total pancreatectomy, completion pancreatectomy after prior pancreas surgery, or (less commonly) distal pancreatectomy.[159] Candidates for a pancreatectomy must have clear evidence that abdominal pain is secondary to pancreatitis based on either recurrent episodes of acute pancreatitis documented by elevated lipase or imaging or a clear diagnosis of chronic pancreatitis by imaging.[11] Calcifications in the pancreas are clearly diagnostic for chronic pancreatitis in a patient with compatible clinical symptoms, but pancreatic calcifications are present only at a late stage of disease.[160] Noncalcific chronic pancreatitis is more difficult to diagnose. Endoscopic ultrasound, magnetic resonance imaging with secretin-stimulated magnetic resonance cholangiopancreatography, and endoscopic pancreatic function tests measuring bicarbonate secretion following secretin stimulation are all recommended for the diagnostic evaluation for noncalcific chronic pancreatitis.[161-163] In the absence of clear preceding history of recurrent acute pancreatitis, two positive diagnostic tests are preferred to establish a definitive diagnosis of noncalcific chronic pancreatitis before proceeding to surgery.[164]

Total pancreatectomy with autoislet transplant is only indicated in patients who continue to have abdominal pain from either chronic pancreatitis or recurrent episodes of acute pancreatitis when the pain is significant enough to interfere with quality of life despite optimal medical care and, when indicated, endoscopic therapy.[11] Although many patients are reliant on chronic opioids to manage pain at the time of total pancreatectomy with autoislet transplant, it is not necessary or recommended to wait for a patient to become opioid-dependent before considering total pancreatectomy with autoislet transplant. A shorter duration of disease, less severe pancreatic fibrosis, and a shorter history of opioid use are all likely to convey a better prognosis for both resolution of pain after surgery and higher islet mass for transplant.[165-168] Total pancreatectomy with autoislet transplant is often preferred over other conventional duct drainage surgeries like a Puestow or Frey for small-duct pancreatitis, children with pancreatitis, and genetic pancreatitis, because of high risks for disease recurrence and technical inability to perform a drainage with a small pancreatic duct.[33,169-172] Patients who have had a prior drainage and/or partial resection procedure are candidates for total pancreatectomy with autoislet transplant to treat pain, but they should be counseled that these prior surgeries impair islet yield, and the risk is high that they will need at least partial supplementation with exogenous insulin lifelong after surgery.[11,173] Distal pancreatic resections are rarely indicated for chronic pancreatitis but might be considered in specific settings—for example, distal pancreatectomy may be performed if pancreatitis is only present in the tail because of a disruption of the mid pancreatic duct. These patients can be considered for an autoislet transplant using the resected portion of the pancreas.

Because total pancreatectomy with autoislet transplant is a major surgical procedure with a physically, emotionally, and cognitively demanding recovery process, medical and psychological comorbidities need to be assessed and managed before surgery.[11] The patient needs to be psychologically and cognitively able to manage exocrine insufficiency and diabetes to be a candidate for surgery. The majority of patients undergoing total pancreatectomy with autologous islet transplant do not have diabetes mellitus before surgery, although most have at least some loss of islet mass because of the fibrotic destruction of exocrine and endocrine tissue that occurs with chronic pancreatitis.[174] Approximately 8% of autoislet transplant recipients will have mild preexisting pancreatogenic diabetes at time of surgery.[11] In these cases autoislet transplant is considered if sufficient C-peptide production can be demonstrated, with the surgical goal to preserve residual β cell mass.[175] Patients with chronic pancreatitis who have no or low C-peptide are not candidates for an islet infusion but can be considered for pancreatectomy alone to treat pain and associated disability, which is the primary goal of the surgery.

Rarely, autologous islet transplantation is also performed at time of extended distal or total pancreatectomy for other benign pancreatic disease, including trauma, benign neoplasm, or, more rarely, premalignant conditions.[176-179] Autologous islet transplantation is not recommended for malignant disease outside the context of a clinical trial because of the risk for establishing new metastatic disease in the liver when residual exocrine tissue is coinfused with the islet product.[180,181]

Surgical Approaches to Autoislet Transplantation

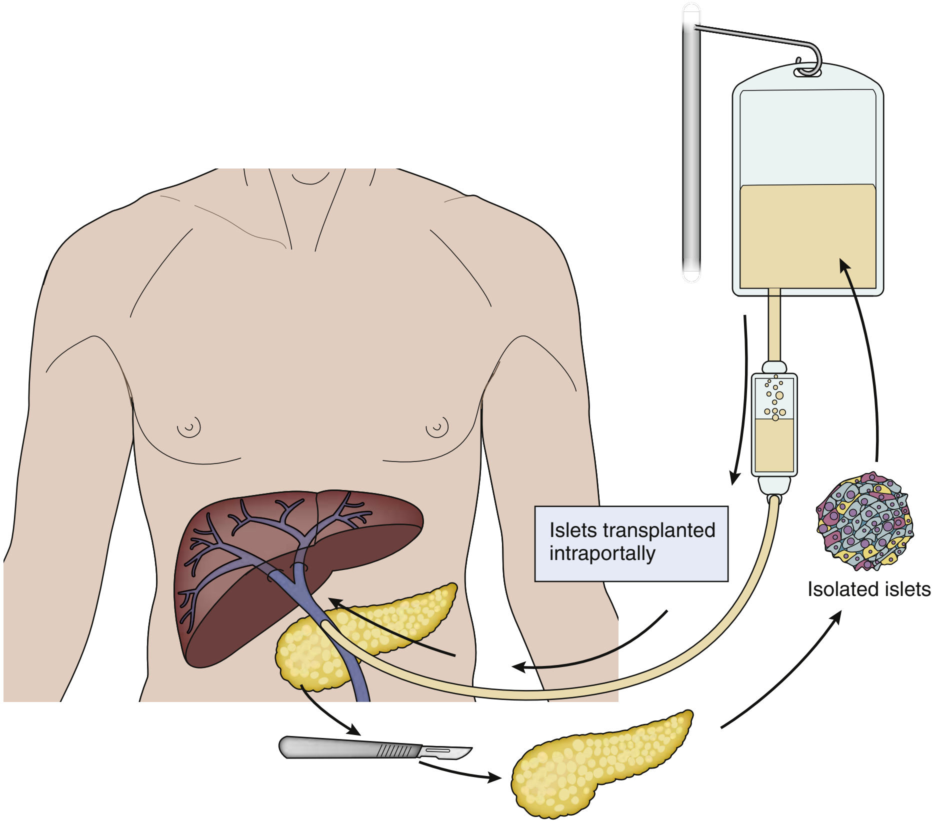
The surgical procedure of total pancreatectomy with autoislet transplantation (Fig. 41.13) carries significantly higher morbidity when compared with an alloislet transplant because of the pancreatectomy and associated anatomic reconstructions (Fig. 41.14).[182] However, the procedures of islet isolation and infusion are technically similar for autoislet and alloislet transplantation, with the exception that higher tissue volume and less pure islet tissue is used for autoislets to maximize islet availability.[183]

For the total pancreatectomy portion of the procedure, the pancreas is entirely resected, taking care to preserve the blood supply to the pancreas for as long as possible to minimize warm ischemia time.[11] Because of the vascular anatomy, the spleen and a portion of the duodenum are also resected. There are several approaches to restoring gastrointestinal and biliary tract continuity following pancreatectomy. Most often the gastrointestinal anatomy is reconstructed with a Roux-en-Y duodenojejunostomy or gastrojejunostomy.[170,172,184] The biliary tract is reanastomosed most commonly via choledochojejunostomy or hepaticojejunostomy.[172] One early surgical approach was end-to-end duodenoduodenostomy with choledochoduodenostomy, but this technique is rarely used in the current era because of a high risk for bile reflux gastritis.[185] In some centers a gastrojejunal or jejunal feeding tube may be placed during surgery to provide nutrition during surgical recovery.[172]

Once the pancreas is resected, it is transported immediately to the islet isolation facility. Islet isolation is most often performed at the same center where the pancreatectomy is occurring, but rarely the pancreas is transported to a remote islet lab for isolation.[186-188] Current data suggest similar or nearly equivalent outcomes with remote versus on-site islet isolation. Similar to the procedures for a cadaveric donor pancreas, the pancreatic duct is cannulated, and a collagenase solution is dispersed through the pancreas parenchyma for enzymatic digestion, followed by mechanical digestion of the pancreas using the semiautomated Ricordi method.[189] Autoislet grafts infrequently undergo a purification step by density centrifugation. Tissue volumes of up to 0.25 mL/kg recipient body weight are considered acceptable for autoislet transplantation, and because purification will reduce islet recovery and result in a lower islet dose transplanted to the patient, it is only used when necessary to reduce tissue volume to an acceptable threshold.[183] Islets can be infused intraoperatively by directly accessing a tributary of the portal vein or can be infused with a percutaneous transhepatic approach with interventional radiology following the surgical procedure.[172,190] As with allogeneic islet transplantation, heparin is administered with the islets and subsequently followed by continuous intravenous infusion or subcutaneous administration to minimize the risk for portal branch vein thrombosis.[11] Intensive insulin therapy is instituted to protect the transplanted islets from the toxic effects of hyperglycemia during the relative hypoxic period of engraftment until revascularization occurs.[10]

Patient and Graft Survival After Autoislet Transplant

The primary rationale for total pancreatectomy with autoislet transplant is to lessen pancreatic pain and improve quality of life.



Islets transplanted intraportally
Isolated islets

Fig. 41.13 **Total Pancreatectomy With Autologous Lslet Transplantation.** The procedure involves removal of the diseased pancreas for collagenase digestion and centrifuge purification in a current good manufacturing practice or current good tissue practice islet isolation facility. The final islet product is transplanted intraportally via the splenic vein stump, a mesenteric artery, or recannulation of the umbilical vein. Multiple centers have demonstrated improved quality of life and reduced opioid use after this procedure, with approximately 50% or more of adults and 80% of children opioid free at 1 year and significantly improved health-related quality of life scores overall.[11,172] Patient survival historically is 95% at 1 year and 72% at 10 years after surgery.[191]

Survival of autoislets has been defined by C-peptide positivity or by insulin independence. Depending on the patient population, insulin independence has been reported in 15% to 40% of patients at time intervals of 1 to 5 years posttransplant.[192] The largest 10-year follow-up cohort reported that 22% of patients were insulin independent at 5 years, and 13% were insulin independent at 10 years.[191] Factors potentially increasing likelihood for insulin independence and durability of insulin independence include younger patient age, higher islet mass transplanted, lack of prior pancreas surgeries, and shorter duration of pancreatitis.[192] At 1 year post–total pancreatectomy with islet autotransplantation, nearly 100% have clinically significant C-peptide (meal-stimulated value ≥0.6 ng/mL) when greater than 5,000 IEQ/kg are transplanted, 97% with 2500 to 5000 IEQ/kg, and 79% with less than 2500 IEQ/kg.[11]

Metabolic Outcomes

As with alloislet transplantation, successful autoislet transplantation with a sufficient number of islets (~350,000 islets or 5000 IEQ/kg body weight) achieves normal or nearly normal levels of fasting blood glucose and HbA1c. However, in the case of autoislet transplantation specifically, a frequent problem following the procedure is hypoglycemia associated with exercise and following high-carbohydrate meals.[193-195] This posttransplant complication is thought to be primarily associated with the use of Roux-en-Y surgery for pancreatectomy. This causes significant alterations in the normal physical relationships between the stomach outlet and the small intestine (Fig. 41.14). This results in a mismatch between glucose and insulin levels, such that the autoislets release excessive insulin given the ambient glucose levels in venous blood early after ingestion and insufficient glucagon during the late postprandial period. Interestingly, failure of an appropriate glucagon response to insulin-induced hypoglycemia seen with intrahepatic autoislet transplantation was not observed when autoislets were transplanted into nonhepatic sites in addition to the usual intrahepatic site (Fig. 41.15).[195] This led to the suggestion to provide autoislet recipients with intact glucagon responses to hypoglycemia by transplanting at least a portion of the autoislets in a nonhepatic site, such as the omentum.[195-197]

Metabolic tests have been used to estimate the number of intrahepatic islets that survive intrahepatic transplantation. The test used most frequently involves glucose potentiation of GPAIS.[196] Intravenous arginine alone can be used in both diabetic and nondiabetic subjects to induce an acute insulin response (see Chapter 32). This response is augmented when a prior glucose infusion is used to elevate blood glucose levels (Fig. 41.16). GPAIS has thus been used to estimate insulin secretory reserve and has been applied to recipients of intrahepatic autoislets. Because these recipients no longer have a native pancreas, insulin responses come exclusively from their transplanted islets. Correlations between the number of intrahepatic islets transplanted and the magnitude of GPAIS responses are significant (Fig. 41.17). The number of islets transplanted is a known value, and the slope of the line reflecting this relationship is close to the theoretical slope observed in normal subjects, therefore this justifies the use of the GPAIS value as an estimate of the number of islets surviving transplantation. Repeated use of GPAIS in the years following islet transplantation may provide a useful estimate of survival of transplanted allo- and autoislets.[117]

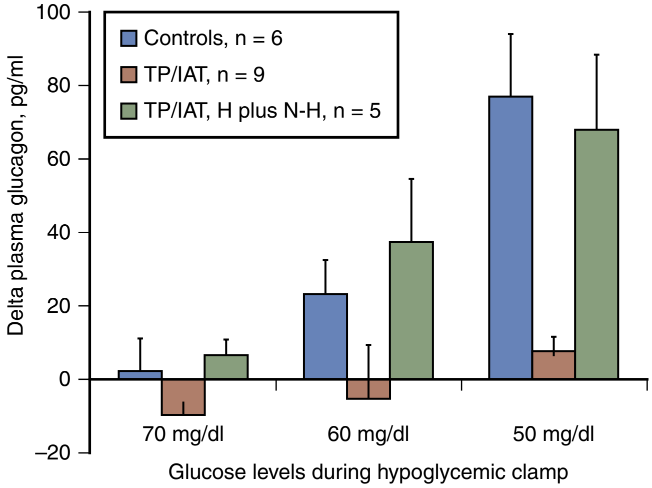

Fig. 41.15 Hypoglycemic clamp studies in patients who underwent total pancreatectomy with islet autotransplantation (*TP/IAT*) demonstrated minimal glucagon responsiveness to hypoglycemia with conventional intraportal islet transplant but restoration of normal glucagon counterregulation when a portion of the islets was transplanted into a nonhepatic site, usually the peritoneal cavity. *H*, Hepatic; *N-H*, nonhepatic site. (Reproduced with permission from Bellin MD, Parazzoli S, Oseid E, et al. Defective glucagon secretion during hypoglycemia after intrahepatic but not nonhepatic islet autotransplantation. *Am J Transplant.* 2014;14:1880–1886.)

Assessment of beta-cell mass and alpha- and beta-cell survival and function by arginine stimulation in human autologous islet recipients. *Diabetes.* 2015;64:565–572.)

KEY POINTS

- Pancreatectomy with islet autotransplantation is indicated for severe, painful forms of chronic and recurrent acute pancreatitis. Most patients exhibit islet graft function (C-peptide–positive), with insulin independence in 15% to 40% of patients and most common with earlier surgical intervention, less pancreatic fibrosis, and high islet mass. Hypoglycemia posttransplant can occur with exercise or high carbohydrate meals because of alterations of the gastrointestinal track (Roux-en-Y reconstruction after pancreatectomy) and failure of an appropriate glucagon response to hypoglycemia.

EFFECT OF SUCCESSFUL PANCREAS OR ISLET TRANSPLANTATION ON COMPLICATIONS OF DIABETES

The risk for microvascular complications in T1DM is mediated by chronic hyperglycemia. Successful pancreas and islet transplantation restores normoglycemia and protects against development of diabetes-related changes in transplanted kidneys.[198,199] Reversal of diabetic lesions in the native kidney is apparent on renal biopsy at 10 years after successful pancreas transplantation.[5] Retinopathy stabilized or reversed in a cohort of 33 patients after pancreas transplant alone, whereas a medically treated control group had progression of retinopathy in 14%.[200] This was consistent with earlier findings in a study comparing fundoscopic changes and the need for further laser treatment in patients receiving kidney alone versus kidney and pancreas transplantation.[201] A similar benefit has been reported for neuropathy, with improved motor, sensory, and autonomic nerve function reported over 10 years after pancreas transplantation.[202] Importantly, this was also associated with a decreased death rate associated with autonomic insufficiency over the same time period.[203] Pancreas transplantation has potential benefits for cardiovascular health, with reduced cardiovascular mortality in pancreas-kidney transplant recipients compared with kidney transplant alone.[204] In a prospectively controlled study, regression of carotid artery intimal thickening was observed in a pancreas and kidney transplant group compared with no regression of arterial lesions in a kidney transplant alone group.[205]

Although the research on secondary diabetes complications after islet transplant is less extensive, available data suggest a similar protective effect against progression of microvascular complications. In a single cohort of 26 patients with type 1 diabetes, islet transplant alone with low-dose tacrolimus and mycophenolate resulted in better preserved renal function when compared with medical treatment (glomerular filtration decline of –1.4 mL/min/year/1.73m^2 vs. –3.6 mL/min/year/1.73m^2), and no patient had progression of retinopathy after islet transplant.[6,79] A separate cohort of patients followed for 5 years after allotransplantation showed improved sensory nerve conduction velocities after 3 years posttransplant.[206]

KEY POINTS

- Successful pancreas or islet allotransplantation stabilizes microvascular complications of diabetes, including retinopathy, nephropathy, and neuropathy. Biopsy-established diabetic nephropathy shows reversal after 10 years of successful pancreas transplantation, and reversal of autonomic neuropathy after pancreas transplant is associated with reduced mortality.

FUTURE DIRECTIONS AND CONCLUSIONS

Because the pool of deceased pancreas donors is limited, to offer transplant therapies to a larger population of patients with diabetes, a renewable cell source will be necessary. The two most promising avenues of research for a replenishable islet supply are porcine islets and stem cell–derived islets.

Adult and neonatal porcine islets have successfully restored insulin independence in nonhuman primate models when treated with conventional immunosuppression plus costimulatory blockade with an anti-CD154 monoclonal antibody (not available for clinical use at time of this writing).[207,208] Porcine xenografts are subject to a robust, instant blood-mediated inflammatory response that may be lessened by genetic manipulation of porcine islets, including development of genetically engineered galactose-alpha1, 3-galactose–deficient donor pigs.[209] Effective immunosuppression or immunoprotection by encapsulation will be necessary for porcine islets to become a therapeutic option for patients. Encapsulation of islets is challenging, as it requires a semipermeable barrier that can prevent immune cells from infiltrating the islet graft while still allowing adequate diffusion of oxygen, nutrients, and insulin.

One concern specific to porcine islets is the risk for transmission of xenotic infectious organisms. The porcine endogenous retroviruses (PERVs) are ubiquitous in pigs, and transmission from porcine to human cells has been demonstrated *in vitro*.[210] However, no transmission of PERV has been observed in very limited early clinical trials in which patients with T1DM received porcine islets microencapsulated in alginate or in subcutaneous collagen-covered macroencapsulation devices.[211,212] Clinical-grade source pigs for islet transplant would need to be housed in a pathogen-free secured environment with routine monitoring for PERV and other infectious organisms.

Stem cell–derived islets are the other promising future source for cell therapy, either by use of embryonic stem cell lines or induced pluripotent stem cells. Embryonic stem cells have the advantage of being a single renewable cell line that can be readily scaled up for large-batch manufacturing, but the disadvantage of posing a higher risk for teratoma transformation, immunogenicity, ethical constraints, and potential unacceptability of therapy for some patients. Embryonic cells reprogrammed *in vitro* to immature pancreatic endocrine progenitor cells (with further maturation *in vivo*) or differentiated *in vitro* into fully mature pancreatic islets with glucose-responsive insulin secretion have both shown success in reversing diabetes in murine models.[213,214] More recently, phase I/II clinical trials have been initiated with encapsulated embryonic stem cell–derived pancreas endoderm cells implanted subcutaneously with an immunoprotective membrane without immunosuppression, or a vascularized membrane with immunosuppression. Embryonic stem cell–derived islets are an allogeneic cell transplant and will require either immunosuppression or encapsulation to prevent rejection.[215]

Induced pluripotent stem cells are derived from a patient's own cells and thus are HLA-identical. Functional β cells have been developed using induced pluripotent stem cells both from nondiabetic controls and patients with T1DM.[216] Although autologous islets or β cells derived from one's own induced pluripotent stem cells offers promise for an immunosuppression-free approach to cell therapy for postpancreatectomy diabetes or T2DM, patients with T1DM would continue to require immunosuppressive treatment or immunoencapsulation to prevent recurrent β cell autoimmunity.

In conclusion, allogeneic whole pancreas and isolated islet transplantation are established procedures for patients with insulin-dependent diabetes complicated by excessive glycemic lability and/or hypoglycemia unawareness experiencing severe hypoglycemia events or by the requirement for immunosuppression in support of another organ transplant, most often a kidney transplant for end-stage diabetic nephropathy. Availability of both procedures is dependent on national and regional expertise and policy governing the regulation of cellular therapy. Most often performed in patients with T1DM, pancreas transplantation is increasingly offered to patients with insulin-dependent T2DM or pancreatogenic forms of diabetes at the time of or following another organ transplant. Islet transplantation offers a minimally invasive alternative to pancreas transplantation that has been used mainly for the treatment of T1DM owing to challenges in isolating and engrafting a sufficient islet mass to eliminate insulin requirements. Both approaches have demonstrated long-term improvement in metabolic control and quality of life and reduction in diabetes-related complications balanced against the risk for immunosuppressive drug therapy. Autologous islet transplantation may be offered to patients requiring total pancreatectomy for treatment of recurrent acute or chronic pancreatitis in order to mitigate or prevent postsurgical diabetes and offers improvement in metabolic control and quality of life without the associated risks of immunosuppression. Future work in genetically engineered porcine islets and human embryonic or inducible stem cell–derived islets offer hope for a one-day inexhaustible supply of islet tissue available for cell therapy to treat diabetes.

KEY POINTS

- β cell replacement therapy with pancreas or islet transplants can restore normoglycemia and prevent acute and chronic complications of disease, but its application is currently limited by the small number of suitable deceased pancreas donors; potential renewable sources of islets in development include human stem cell–derived islets and xenogeneic porcine islets.

HISTORY

Although the term "diabetes" was initially used by Aretaeus of Cappadocia, the first Greek physician to accurately describe the symptoms of diabetes, in the second century of the Common Era, the first known description of the disease is in the Ebers Papyrus, dating 1552 BCE.[1] It was not until the nineteen century that the initial descriptions of diabetic complications started to appear in the literature,[2] but several characteristic diabetic complications started to gain recognition with the discovery of insulin and the long-term survival of diabetic patients.[3-5] Initially, patients with longstanding diabetes were observed to have a high incidence of heart disease and atherosclerosis,[2,6] but in the 1950s the concept of a specific diabetic angiopathy was proposed, consisting of retinopathy, nephropathy, coronary artery disease (CAD), and peripheral vascular disease,[6] and the frequent triad of retinopathy, nephropathy, and neuropathy was also described.[7] Multiple theories were proposed to account for these vascular lesions observed in diabetic patients, however the observation that patients with "poor control" (as defined by symptoms of polydipsia and polyuria, frequent glycosuria, and ketosis) had a higher incidence of complications strongly suggested that these complications could be prevented by increasing the control of the metabolic disturbances associated with diabetes.[8,9] With these data and clinical observations in mind, Dr. Elliott P. Joslin already wrote in 1950 that "these young patients must be told that if they do not keep their diabetes controlled they are liable to serious complications in their eyes, their kidneys, their hearts or their brains."[10] However, debate regarding the role of diabetic control, or, more precisely, glycemic control, on the pathogenesis of diabetic complication persisted for several decades. Until the late 1970s groups of investigators were openly debating whether good diabetic control had any role in the prevention of the vascular complications of diabetes.[11,12]

CLASSIFICATION

Long-term complications of diabetes can be divided into *microvascular*, or diabetes-specific, due to damage to capillaries and small vessels (retinopathy, nephropathy, and neuropathy, described in detail later in Chapters 43, 44, and 45) and *macrovascular*, reflecting the increased risk of accelerated atherosclerosis with its clinical manifestations such as CAD, cerebrovascular accident (CVA), and peripheral vascular disease. These complications are responsible for the increased morbidity and mortality associated with both type 1 and type 2 diabetes.[13-19] However, other long-term complications of diabetes, including certain rheumatic manifestations, increased susceptibility to some infections, and some skin disorders, have also been reported, some with higher incidence in patients with diabetes and others that occur almost exclusively in diabetic patients. Although these complications are less well known, they can have a significant impact on morbidity and mortality, with survival studies having shown an increased incidence of death from cancer [19] and infectious diseases[19,20] in diabetic patients.

Rheumatic, Dermatologic, and Infectious Manifestations

Several rheumatic manifestations of diabetes mellitus have been described, affecting up to 30% of diabetic patients.[21] Although the majority of these syndromes are not specific to diabetic patients, but occur more frequently in them (e.g., adhesive capsulitis of the shoulder, Dupuytren disease, flexor tenosynovitis), diabetic cheiroarthopathy or "syndrome of limited joint mobility" is a diabetes-specific complication characterized by painless limitations of multiple joints in the hand and skin changes similar to those seen in scleroderma, with thick and rigid skin.[21,22]

The increased susceptibility to infections in patients with diabetes was already described by Elliott Joslin in 1950,[10] but more contemporary studies have shown that diabetic patients are more prone to certain specific infections and organisms, among them respiratory tract infections (*Staphylococcus aureus, Streptococcus pneumoniae, Mycobacterium tuberculosis*) and urinary tract infections (bacteriuria and upper urinary tract infections, as well as fungal infections).[23] The reasons for this predisposition are not known, however several studies, mostly in animal models of diabetes, have focused on impaired neutrophil function; the data are inconclusive at best.[24] Fournier gangrene, a fulminant form of infective necrotizing fasciitis of the perineal, genital, or perianal regions, as well as other forms of necrotizing fasciitis have diabetes as the major risk factor,[25] and an increased prevalence and severity of periodontal disease has been described in diabetic patients.[26] Some infections seem to occur almost exclusively in patients with diabetes, including invasive (or malignant) otitis externa caused by *Pseudomonas aeruginosa* in most cases, rhinocerebral mucormycosis caused by *Rhizopus oryzae*, with ketoacidosis being the most important risk factor, and emphysematous infections such as emphysematous cholecystitis and pyelonephritis.[23]

Necrobiosis lipoidica is a characteristic skin lesion associated with diabetes and consists of bilateral, hyperpigmented plaques on the anterior tibial surface with telangiectasias and violaceous/brown periphery. Together with bullosis diabeticorum (asymptomatic bullae containing sterile fluid, usually present on the dorsa and sides of lower legs and feet), they are cutaneous manifestations of diabetes. Moreover, patients with diabetes also have a higher prevalence of other dermatologic conditions, including ichthyosiform skin changes, thick, scleroderma-like changes of the hands and fingers, and toenail onychomycosis.[27,28]

KEY POINTS

- Diabetic complications can be divided into microvascular (retinopathy, nephropathy, and neuropathy) and macrovascular (increased incidence of coronary artery disease, cerebrovascular disease, and peripheral arterial disease).
- Diabetes is also associated with rheumatic (adhesive capsulitis, Dupuytren disease, and flexor tenosynovitis), dermatologic (necrobiosis lipoidica and bullosis diabeticorum), and infectious manifestations (Fournier gangrene, malignant otitis externa, and rhinocerebral mucormycosis).

EPIDEMIOLOGY

The prevalence of the microvascular complications of diabetes is associated with duration of disease and degree of glycemic control. An early prospective study of more than 4000 diabetic patients followed for 25 years in Brussels, Belgium showed that the prevalence of retinopathy and neuropathy in patients who had had diabetes for 25 years was more than 50%, whereas the prevalence of diabetic nephropathy was significantly lower, at 14%.[29] More recent epidemiological studies have confirmed these initial data: after several decades of diabetes, the majority of patients will have at least some mild retinopathy and neuropathy, whereas only a subset of genetically predisposed subjects will develop diabetic nephropathy.

Large epidemiological and clinical trial studies have shown that the prevalence of any diabetic retinopathy approximates 80% after 30 years of diabetes, whereas the prevalence of vision-threatening proliferative retinopathy is around 30% to 50%.[30,31] These values are heavily influenced by the degree of metabolic control, as shown by the Diabetes Control and Complication Trial (DCCT), with 50% of type 1 diabetic patients having proliferative retinopathy after 30-year disease duration in the conventional treatment cohort and 21% in the intensive therapy cohort.[31] The data for peripheral neuropathy are similar. The DCCT experience showed that, after 25 years of type 1 diabetes, 61% of patients had abnormal nerve conduction, and 37% of patients had clinically significant neuropathy,[32] a percentage similar to other epidemiological studies in Europe (28% in the EURODIAB IDDM Complications study and 37% in a large multicenter study conducted in the United Kingdom).[33,34]

The epidemiology of diabetic nephropathy is significantly different from that of the other microvascular complications of diabetes, with fewer diabetic patients being affected by renal problems than other complications. Data from the DCCT/Epidemiology of Diabetes Interventions (EDIC) study in young type 1 diabetic patients show that, after 30 years of type 1 diabetes, only 25% of conventional treatment patients and 9% of intensive therapy patients showed microalbuminuria or worse renal outcomes.[35] Data from type 2 diabetic patients older than 40 years of age in the United States showed a frequency of microalbuminuria of 35% versus 12% of the nondiabetic population.[36] Although it is not clear why there is a difference in the epidemiology of these microvascular complications, evidence from familial aggregation studies, ethnic specific prevalence rates, and, more recently, genetic studies, has shown that the development of diabetic complications is at least partially under the control of genetic factors, with several candidate genes having been identified.[37,38]

It is well known that cardiovascular disease (CVD) is the leading cause of death in patients with both type 1 and type 2 diabetes, and that the prevalence of CVD is increased by the disease. CAD, peripheral artery disease, and CVD rates are increased 2- to 4-fold in diabetic patients, with a higher relative risk in women than in men. Moreover, in most studies, clinical outcomes of CVD are worse in patients with diabetes as compared with nondiabetic subjects.[39,40] Whereas type 2 diabetes is associated with metabolic changes that are known to have a proatherosclerotic profile (obesity, hypertension, dyslipidemia), recent studies have shown that the risk of CVD is similar in type 1 and type 2 diabetes, although the relative role of diabetic-specific risks could be different in type 1 versus type 2 diabetes.[41,42] In type 1 diabetes the essential role of diabetic nephropathy as a risk factor for CVD is well established and has been demonstrated in several studies that have shown mortality in type 1 diabetic patients without microalbuminuria or more severe stages of renal disease similar to that observed in the nondiabetic population.[43,44]

As a consequence of the high rate of CVD and overall diabetic complications, mortality rates are increased in diabetic patients, both in the younger and older populations. In the Framingham Heart Study, individual with diabetes and a mean age of 60 years were shown to have a 2-fold increase in all-cause mortality and a 3-fold increase in CVD mortality compared with the nondiabetic population.[45] A recent study in Sweden of young diabetic patients (15 to 34 years of age) showed a 2- to 3-fold increase in mortality rates.[46] There is a significant difference in type 1 versus type 2 diabetes, with type 2 diabetic patients having a double hazard ratio (HR) for total mortality as compared with age-matched type 1 diabetic patients,[46,47] and this is likely because of the marked excess in macrovascular diabetic complications found in the type 2 diabetic population.[47]

Significant improvements in diabetes management over the last several years regarding glycemic control and cardiovascular risk factors management have resulted in a changing pattern of diabetic complications. Observational and epidemiological studies have demonstrated a decreased incidence of severe retinopathy, nephropathy and end-stage renal disease, neuropathy, CVD, and overall mortality in patients with a recent diagnosis of diabetes as compared with patients with an earlier diagnosis, likely the result of decreases in glycated hemoglobin (HbA1c), blood pressure, low-density lipoprotein (LDL) cholesterol, and smoking status.[48-51] Unfortunately, while the incidence of advanced complications is decreasing, there is an epidemic of obesity and type 2 diabetes, which means that the overall numbers of diabetic patients reaching the stage of late microvascular and macrovascular complications is increasing, putting a strain on healthcare resources.

KEY POINTS

- Although diabetic retinopathy and neuropathy are present in most patients with more than 25 years of diabetes, diabetic nephropathy is only present is less than 25% of patients with long diabetes duration and is likely under the control of genetic factors.
- The prevalence of cardiovascular disease is increased by 2- to 4-fold in patients with diabetes, with a higher relative risk in women than men.

PATHOPHYSIOLOGY

It has long been known that exposure to the diabetic milieu is responsible for the pathogenesis of the microvascular complications of diabetes, and among the multiple metabolic abnormalities observed in diabetic patients chronic exposure to high glucose levels is the common feature of all forms of diabetes. Animal models of diabetes have also helped to support the hypothesis that high glucose levels are responsible for the vascular complications. Galactose-fed dogs develop retinopathy that is histologically identical to diabetic retinopathy, thus suggesting that high hexose levels are by themselves able to cause retinopathy[52]; and good glucose control achieved by insulin injections or islet cell transplantation reduces the incidence and severity of retinopathy and nephropathy in dogs and rats, respectively.[53-54]

To elucidate the mechanisms by which high glucose levels are toxic to the small vessels, multiple animal models have been studied, with the most commonly used ones being rodents. Rodents made diabetic by the use of the toxic drugs streptozotocin or alloxan or by pancreatectomy are useful models of insulin-deficient diabetes. Genetically altered models such as db/db mice (leptin receptor mutation) and ob/ob mice (leptin mutation) have been used to mimic the abnormalities seen in obesity and type 2 diabetes. Although these rodent model have been very useful in the study of diabetic complications, they do not completely resemble their human counterparts. Rodents do not usually exhibit the more advanced lesions of diabetic nephropathy (nodular glomerulosclerosis), retinopathy (preretinal neovascularization and retinal neuron degeneration), or neuropathy (segmental demyelination and fiber loss).[55] Larger animals have also been studied as models for the vascular complications of diabetes, including dogs (alloxan, pancreatectomy, or galactose-fed), cats, pigs, and nonhuman primates, animals that have a macula like humans and can be used for the study of diabetic maculopathy. However, these larger animal models of diabetic complications have disadvantages, such as long time lags before the development of diabetic lesions (studies in dogs have been performed after 5 years of diabetes and in monkeys up to 15 years later) and the absence of advanced retinopathy (no neovascularization or neuronal damage).[56]

Although there is universal agreement that high glucose levels cause the microvascular lesions of diabetes, the exact molecular mechanisms by which glucose levels induce vascular damage are still not completely understood. It is well known that several molecular pathways are activated by high glucose levels in cell cultures or animal models of diabetes, including increased flux in the polyol pathway, increased formation of advanced glycation end-products (AGEs), activation of protein kinase C (PKC), and increased flux in the hexosamine pathway.[57] More recently, a common element between these pathways has been found in the increased production of reactive oxygen species (ROS) in the mitochondria and overall increased oxidative stress induced by hyperglycemia[57-59]; these changes have been linked to the activation of transforming growth factor β signaling, decreased activity of endothelial nitric oxide synthase, decreased activity of prostacyclin synthase, and increased activity of several proinflammatory pathways.[58-59]

The role of increased mitochondrial ROS production in explaining the phenomenon called *metabolic memory* (another phenomenon in the pathogenesis of diabetic vascular complications) has also been recently postulated and supported by experimental data. It has long been known that high glucose levels in tissue culture lead to changes in gene expression that are then perpetuated *in vitro*.[60] In experimental animal models of diabetes, the same phenomenon has been described, with retinopathy progressing even with good glycemic control after an initial period of poor control.[61] Recent data from randomized clinical trials such as the DCCT have shown that the benefits from tight glucose control in terms of reduction in diabetic complications persist for several years, thus confirming that glycemic or metabolic memory also occurs in clinical diabetes.[62,63] Epigenetic modifications such as DNA methylation and histone posttranslational modifications can be induced by oxidative stress and have been detected in models of diabetic complications.[64,65] More recently, epigenetic changes in lymphocytes and monocytes from DCCT patients have been reported, thus confirming the potential role of high glucose–induced changes in chromatin structure in the pathogenesis of the clinical complications of diabetes.[66]

Specific inhibitors of these pathways have been used for more than 30 years in an attempt to find pharmacological agents that could prevent or delay the development of the vascular complications of diabetes. Although successful in preclinical animal studies, the clinical trials of such agents in diabetic patients have been disappointing, and none of them has made it to clinical use. Clinical trials of aldose reductase inhibitors have been performed for more than 30 years, but a recent metaanalysis showed no statistically significant difference in placebo-controlled trials of diabetic neuropathy.[67] AGE inhibitors have also been studied for many years, again with either significant side effects or no efficacy.[68,69] A PKC inhibitor was also shown not to have statistically significant efficacy in diabetic retinopathy in phase 3 studies[70] and was dropped from commercial development. More recently, benfotiamine, an agent shown to inhibit three of the proposed pathways in the pathogenesis of diabetic complications (hexosamine pathways, PKC activation, and AGE formation) was also found to have no effect in diabetic neuropathy.[71] While research in this field continues, these results have underlined the difficulties of translating results from animal models of diabetic complications to clinical use, as well as the long timeline involved in bringing new agents to therapeutic use.

KEY POINTS

- High glucose levels lead to multiple biochemical changes in vascular cells, including increased production of reactive oxygen species.
- Specific inhibitors of these biochemical pathways have been studied in animal models of diabetes but have not been successful in preventing vascular disease in patients with diabetes.

ROLE OF GLUCOSE CONTROL IN THE PREVENTION OF DIABETIC COMPLICATIONS

Poor glycemic control has been associated in early studies with increased severity of microvascular complications,[29] but it was not until the early 1980s that, with the introduction of home glucose monitoring, widespread use of HbA1c measurements, and the use of insulin pump therapies, some initial small clinical trials suggested the possibility that tighter glucose control could prevent or delay the vascular complications of diabetes.[72] However, it was the seminal DCCT, whose results were published in 1993, that definitively established the essential role of tight glucose control in preventing or delaying the microvascular complications of diabetes.[73] This study, initiated in 1983, was designed to answer the question of whether intensive diabetes management would affect the development (in a primary prevention cohort of 726 type 1 diabetic patients with no complications and only 1–5 years of diabetes duration) or delay the progression (in a secondary intervention cohort of 715 type 1 diabetic patients with at least one microaneurysm but no more than moderate nonproliferative retinopathy and duration of diabetes of 1–15 years) of the microvascular or neurological complications of diabetes. Patients were randomly assigned to conventional treatment (in 1983 defined as 1–2 daily injections of insulin, daily blood glucose monitoring, and the goal of avoiding hypoglycemia or hyperglycemia symptoms) or intensive therapy (goal of achieving blood glucose levels as close to nondiabetic range as possible, including fasting values of 70–120 mg/dL, postprandial levels <180 mg/dL, and HbA1c levels in the nondiabetic range). To achieve these goals, intensive therapy patients used three or more insulin injections per day or insulin pump therapy. Over the 6.5-year mean follow-up time, compliance was excellent, with subjects adhering to assigned treatment 97% of study time and more than 99% of subjects completing the trial. The separation between groups in terms of HbA1c was excellent, at approximately 2%, with the conventional treatment group maintaining their HbA1c at approximately 9%, while the intensive therapy group achieved a nadir HbA1c of 6.9% at 6 months and then maintained it at approximately 7% for the remainder of the time (Fig. 42.1).

The results published in the initial report showed a 76% and 54% risk reduction for retinopathy in the primary prevention and secondary intervention groups, respectively (Fig. 42.2) and a risk reduction of 39% for microalbuminuria, 54% for albuminuria, and 60% for clinical neuropathy, at the cost of a 3-fold increase incidence of severe hypoglycemia.[73,74] Although 65% of patients in the intensive therapy group had at least one episode of severe hypoglycemia by study end, as compared with 35% of patients in the conventional therapy group,[74] the data showed no deterioration in quality of life for patients undergoing intensive treatment.[75] More detailed analysis of diabetic complications showed favorable results in almost all subgroups of patients, as defined by gender, age, and other baseline characteristics, in terms of retinopathy, nephropathy, peripheral neuropathy, and autonomic neuropathy.[76-79] The small number of macrovascular events was not statistically decreased by intensive therapy, but some cardiovascular risk factors improved.[80] Moreover, the mean HbA1c levels during the trial were the most significant predictor for the development of complications, with no level of glycemic control below which the risk of complications was eliminated, and there was a 44% risk reduction in the development of retinopathy for each 10% decrease in HbA1c levels (Fig. 42.3).[81]

At the end of the DCCT trial, all participants in the conventional treatment arm were offered training in intensive therapy, and then diabetes care was returned to the subjects' own doctors. The entire group was followed in the EDIC observational study, which started in 1994 and published the 30-year follow-up data.[82] Although HbA1c was nicely separated in the two groups at the end of the DCCT (mean 9.1% in the conventional therapy group vs. mean 7.2% in the intensive therapy group), the difference in HbA1c between the two groups disappeared during the 20 years of EDIC follow-up, and the mean HbA1c overall for both groups at the end of the EDIC study was 8.0%. The significant differences in complications observed at the end of the DCCT and the subsequent disappearance of the difference in glycemic control between the two groups would have logically predicted a parallel development in complications during the

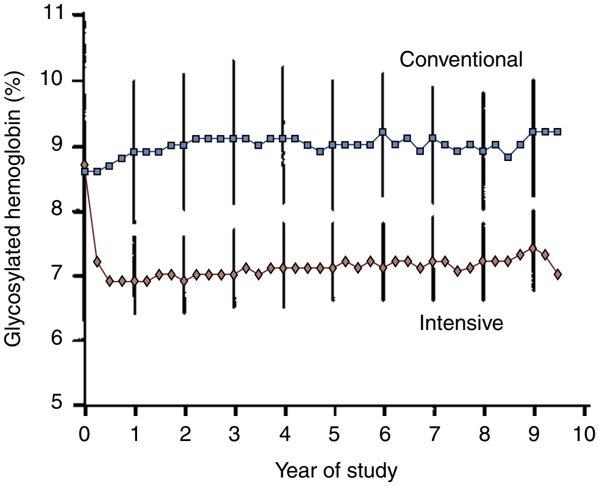

Fig. 42.1 Glycated hemoglobin results from the Diabetes Control and Complications Trial (DCCT). Medians of all quarterly measurements with the 25th and 75th percentiles of the yearly values (*vertical lines*) are shown. The differences between treatment groups became significant by 3 months and remained significantly different over the course of the study (*P* < .001). (From Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med.* 1993;329:977–986.)

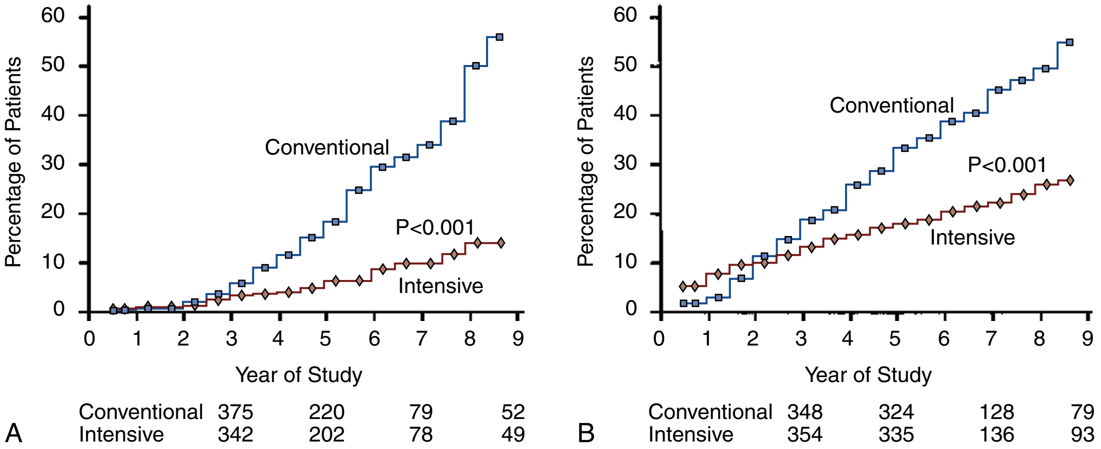

Fig. 42.2 Cumulative incidence of Diabetes Control and Complications Trial primary retinopathy outcomes (three-step change in retinopathy from baseline value, sustained for at least 6 months) measured by fundus photography, comparing intensive and conventional therapy groups. **A,** In the primary prevention cohort, intensive therapy reduced the cumulative incidence by 76% (*P* < .001). **B,** In the secondary intervention cohort, intensive therapy reduced the cumulative incidence by 54% (*P* < .001). (From Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med.* 1993;329:977–986.)

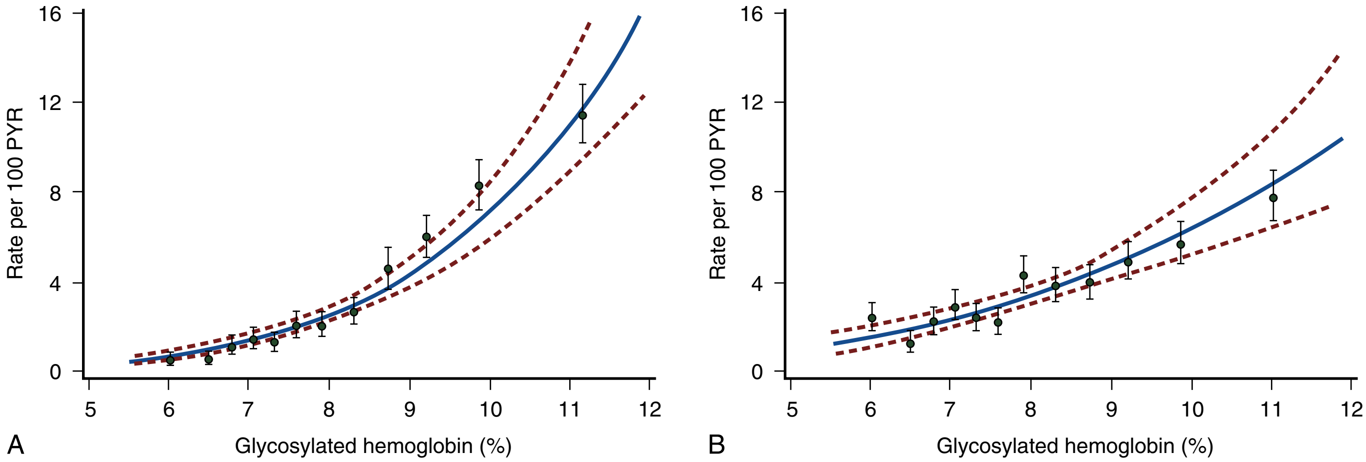

Fig. 42.3 Relationship between updated mean glycated hemoglobin levels and complications in the Diabetes Control and Complications Trial, with examination of combined treatment groups with Poisson regression models (95% confidence bands shown with *dashed lines*). The relationship between mean HbA1c and complications is continuous over the entire range of HbA1c levels, with no inflection or break point at levels of HbA1c above the nondiabetic range. **A,** Risk for sustained (for at least 6 months) retinopathy progression measured as rate per 100 patient-years (PYR). **B,** Risk for developing microalbuminuria (rate per 100). (From Diabetes Control and Complications Trial Research Group. The absence of a glycemic threshold for the development of long-term complications: the perspective of the Diabetes Control and Complications Trial. *Diabetes*. 1996;45:1289–1298.)

EDIC observational study. However, during the initial years of the EDIC there was a further widening in the differences in microvascular outcomes, referred to as “the metabolic memory phenomenon.”[83] The most recent data from the DCCT/EDIC study show that, after a 30-year duration of diabetes, good glycemic control during the interventional trial resulted in an approximately 50% reduction in microvascular complications[84,85] (Fig. 42.4) and a 57% reduction in clinically significant cardiovascular events (nonfatal myocardial infarction, stroke, or death from CVD).[86]

Whether the lessons from the DCCT/EDIC could be applied to type 2 diabetic patients, and whether different therapies for the management of type 2 diabetes would provide advantage in terms of reduced complications was the goal of the seminal United Kingdom Prospective Diabetes Study (UKPDS), which was planned in the 1970s and published in 1998.[87,88] Although a much smaller clinical trial in a Japanese population of type 2 diabetic patients showed results almost identical to the DCCT trial,[89] the patient population (lean type 2 diabetic patients using much less insulin than the DCCT cohorts used) was thought not to be representative of the majority of type 2 diabetic patients. The UKPDS study randomized approximately 4000 newly diagnosed type 2 diabetic patients to conventional treatment (dietary intervention) versus intensive treatment with one of three different sulphonylureas, insulin, or metformin. However, because of the progressive β cell dysfunction characteristic of type 2 diabetes[90] and the stepwise design of the study, a significant proportion of patients initially assigned to diet, sulphonylureas, or metformin ended the study with another added medication, making the assessment of whether one therapy was better than other impossible. The study achieved a 1% separation in HbA1c levels between the conventional and intensive therapy groups. However, after an initial decline from a baseline of 7%, HbA1c levels rose continuously over the 10 years following randomization. Although the median HbA1c over the 10-year study was 7% versus 7.9%, during the last period the HbA1c had increased to 8.1% and 8.7% in the intensive and conventional groups, respectively.[87] The study design and the data analysis were somewhat controversial,[91] however, the overall findings showed that intensive treatment improved microvascular outcomes (driven by a decrease in the need for retinal photocoagulation) but did not affect cardiovascular outcomes, and that there were no clear differences between the different intensive therapies. Of interest, a similar relationship between glycemic control and retinopathy was observed in the UKPDS and in the DCCT; for each 1% decrease in HbA1c, there was a 39% decrease in the risk for retinopathy.[92]

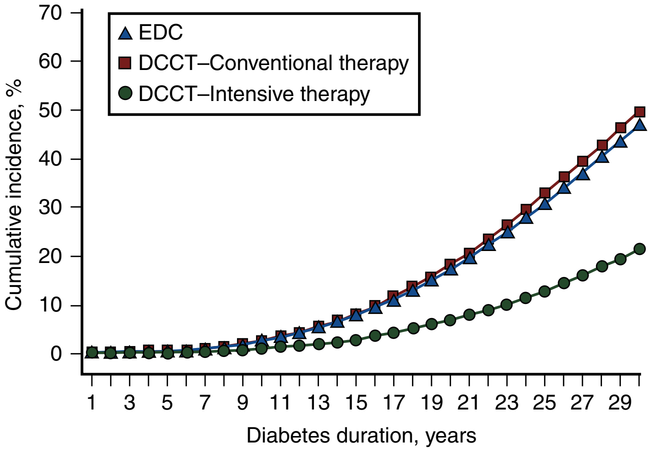

Fig. 42.4 Cumulative incidence of any major eye disease end point in relation to diabetes duration. Diabetes Control and Complications Trial (DCCT) conventional therapy groups (*squares*) and intensive therapy groups (*circles*) are presented. Also presented is the cumulative incidence of these major eye disease points observed in the observational Pittsburgh Epidemiology of Diabetes Complication (EDC) study (*triangles*). (From Nathan DM, Zinman B, Cleary PA, et al.; Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Research Group. Modern-day clinical course of type 1 diabetes mellitus after 30 years’ duration: the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications and Pittsburgh Epidemiology of Diabetes Complications experience (1983– 2005). Arch Intern Med 2009;169:1307–1316.)

At the end of the UKPDS study, follow-up questionnaires were sent annually for 10 years, and, although differences in the HbA1c levels between the two groups were lost at the end of the study, the risk reduction in terms of microvascular events remained significant. A reduction in myocardial infarction and death from any cause became significant, likely secondary to the increased number of events.[93] Thus, a "memory" effect of good glycemic control was observed in type 2 diabetic patients as well, similar to the results of the DCCT/EDIC study in type 1 diabetic patients.

KEY POINTS

- Intensive glucose control has been demonstrated to decrease the risk of microvascular complications in patients with type 1 and type 2 diabetes.
- The effects of several years of tight glucose control persist for many years, the so-called "metabolic memory phenomenon."

ROLE OF GLUCOSE CONTROL IN THE PREVENTION OF CARDIOVASCULAR DISEASE

The role of tight glucose control in the prevention of CVD is still an unresolved issue. Although large amounts of epidemiological data show a tight link between glycemic levels and cardiovascular outcomes, the data from randomized controlled trials are more contradictory. In newly diagnosed type 1 diabetic patients studied in the DCCT/EDIC trial, it took 17 years of follow-up to detect a statistically significant decrease in cardiovascular events in the intensive therapy group,[86] whereas in newly diagnosed type 2 diabetic patients studied in the UKPDS trial a statistically significant decrease in myocardial infarction was observed only 20 years after randomization.[93] More recently, three large randomized clinical trials have been performed with the goal of determining whether achieving normal glycemic control in type 2 diabetic patients at high risk for CVD would result in a reduction in cardiac events [94-96]; unfortunately, the results have been somewhat unexpected. The Action to Control Cardiovascular Risk in Diabetes study randomized more than 10,000 type 2 diabetic patients with a median duration of diabetes of 10 years and either previous cardiovascular events (35% of the group) or two other cardiovascular risk factors to standard therapy (target HbA1c of 7.0%–7.9%) or intensive therapy (goal HbA1c of <6.0%). After 3.5 years of follow-up the study was terminated early because of increased mortality in the intensive therapy group, while the primary outcome was not statistically different between the two groups. The HbA1c separation between the two groups was good, with a median of 7.5% in the standard treatment and a median of 6.4% in the intensive therapy group.[94] Not surprisingly, the intensive therapy group was characterized by a 3-fold increase in the incidence of severe hypoglycemia and a doubling of patients gaining more than 10 kg.[94] At study end, after the intensive therapy group was terminated but patients were followed for up to 5 years, the use of intensive therapy reduced nonfatal myocardial infarctions but increased total mortality.[95] Of interest, the tighter control in the intensive group was achieved with multiple glucose-lowering drugs, including insulin and oral agents. Moreover, the effects of intensive therapy on microvascular disease were less evident than in prior studies of newly diagnosed type 2 diabetic patients, with no reductions in retinopathy, although there was a decrease in cataract extractions, some improvements in neuropathy, and delayed onset of albuminuria.[96] The cause of the excess mortality associated with intensive therapy has still not been identified, however, subsequent analysis found the effect to be robust and observed in most subgroups.[97] The Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation trial randomized 11,000 type 2 diabetic patients with duration of diabetes of approximately 8 years and history of CVD or at least one risk factor for vascular disease to standard glucose control (target HbA1c by local guidelines) or intensive glucose control (target HbA1c of <6.5%) achieved with the addition of glicazide 30 to 120 mg daily. After a median follow-up of 5 years, mean HbA1c levels were 7.3% and 6.5% in the two groups, respectively, but there was no effect on major macrovascular disease or death from any cause.[98] The two groups were then followed for an additional 6 years after trial end, and no differences were observed in the rate of macrovascular disease or death from any cause, consistent with the findings of the original trial.[99] The Veterans Affairs Diabetes Trial was a similarly designed trial, smaller in size (almost 1800 type 2 diabetic patients randomized), in type 2 diabetic patients with an 11-year history of diabetes, 40% with CVD. After a median follow-up of 5.6 years, and despite robust difference in HbA1c level (8.4% in standard therapy and 6.9% in the intensive therapy group), there was no significant difference in the primary or secondary cardiovascular outcomes.[100] After the conclusion of the trial, participants were followed for an additional 5 years, with both groups showing a difference in HbA1c levels of only 0.2% to 0.3% at the end of follow-up. At the end of the observation period the intensive therapy group showed a significant decrease in the composite primary cardiovascular outcome (HR 0.83, $P = .04$) but no reduction in cardiovascular mortality.[101]

The results of these studies suggest that aggressive management of hyperglycemia may not be appropriate in all diabetic patients; but in certain populations, especially older adults and patients with established microvascular disease, a less stringent HbA1c goal would be appropriate. Moreover, in patients with established CVD, tight glucose control does not seem able to decrease CVD outcomes, but still plays a role in the beneficial effects on microvascular disease.

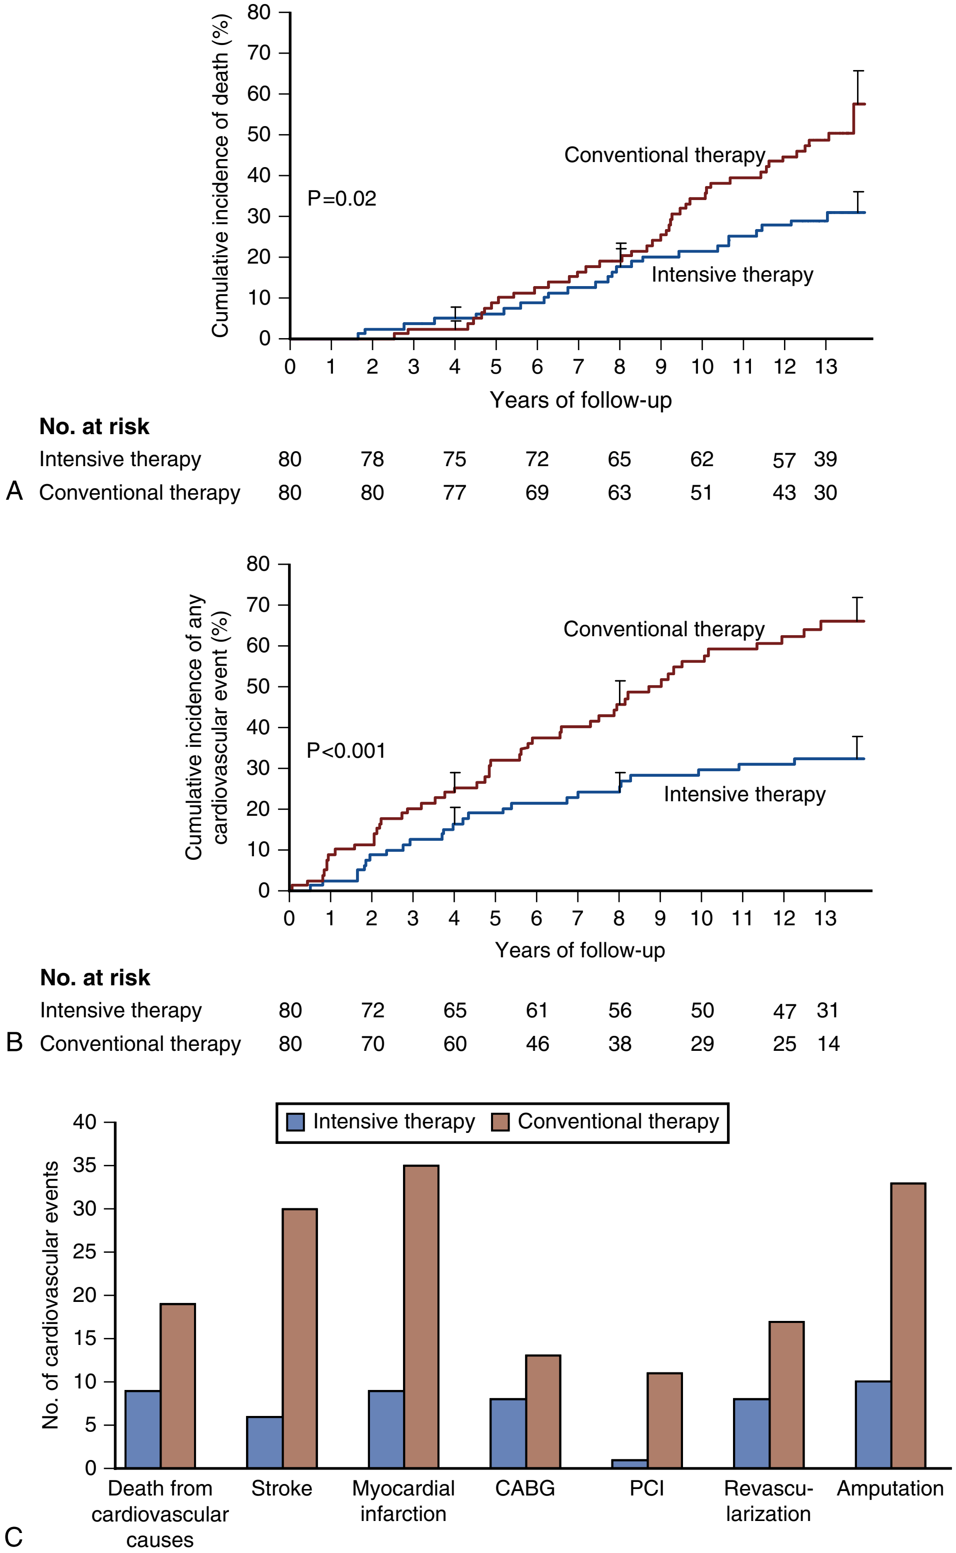
KEY POINTS

- Intensive diabetes treatment leads to a reduction in the incidence of cardiovascular disease in patients with newly diagnosed diabetes but requires a much longer time to take effect than it does for glucose control to have a positive effect on the incidence of microvascular disease.
- Tight glucose control is not effective in reducing cardiovascular disease in patients with long duration of diabetes and may be linked to higher mortality.

CAN WE PREVENT MACROVASCULAR DISEASE?

Although randomized clinical trials evaluating the effects of tight glucose control have shown that CVD can be prevented after a long period of normoglycemia in patients with newly diagnosed type 1 or type 2 diabetes,[80,86,93] multiple other risk factors predispose diabetic patients to CVD, and it is therefore not surprising that interventions addressing multiple risk factors could be more effective in reducing the burden of CVD in these patients. One study that has proven this point is the small Steno type 2 randomized study conducted in Denmark in the 1990s. A total of 160 type 2 diabetic patients with a mean age of 55 years and a duration of diabetes of 6 years were randomized in this open, parallel trial to standard treatment (according to the 1988 recommendations of the Danish Medical Association) or intensive multifactorial intervention (diet and exercise, counseling on smoke cessation, captopril 50 mg twice/day, vitamin C 250 mg/day, vitamin E 100 mg/day, aspirin 150 mg/day for patients with history of CVD) plus intensification of therapy with stricter goals for blood pressure, HbA1c, and fasting LDL cholesterol.[102] At the end of 3.8 years of follow-up, there were statistically significant differences in HbA1c, systolic blood pressure, and cholesterol levels, and these changes led to a significant decrease in microvascular complications.[102] The study continued for another 5 years of follow-up, during which intensive therapy patients maintained a 0.7% decrease in HbA1c, a 11-mm Hg decrease in systolic blood pressure, and a 30-mg/dL decrease in LDL cholesterol, and this led to a greater than 50% reduction in a primary composite cardiovascular endpoint (death from CVD, nonfatal myocardial infarction, coronary artery bypass grafting, percutaneous coronary interventions, nonfatal stoke, amputations, or vascular surgery for peripheral vascular disease).[103]

After the end of this interventional study, these patients were observed in a follow-up study for another 5.5 years, during which the differences in metabolic parameters narrowed and lost statistical significance. Intensive treatment was, however, associated with a significant decrease in total and cardiovascular mortality, with HRs of 0.43 and 0.41, respectively, and the decrease in cardiovascular events was seen in all categories, from stroke and myocardial infarction to amputation[104] (Fig. 42.5).



No. at risk (A)

Intensive therapy	80	78	75	72	65	62	57	39
Conventional therapy	80	80	77	69	63	51	43	30

No. at risk (B)

Conventional therapy	80	70	60	46	38	29	25	14

Fig. 42.5 A, Kaplan-Meier estimates of the risk for death from any cause and B, of the incidence of any cardiovascular events (death from cardiovascular causes, nonfatal stroke, nonfatal myocardial infarction, coronary artery bypass grafting [CABG], percutaneous coronary intervention [PCI], revascularization for peripheral atherosclerotic artery disease, and amputation). The bars represent standard error. C shows the number of events for each component of the composite end point. (From Gaede P et al. N Engl J Med. 2008;358:580-591.)

KEY POINTS

- A combined approach to the prevention of cardiovascular disease by lowering glycated hemoglobin, blood pressure, and low-density lipoprotein cholesterol has been shown to successfully reduce cardiovascular disease, cardiovascular mortality, and total mortality.

EFFECTS OF SPECIFIC HYPOGLYCEMIC AGENTS ON CARDIOVASCULAR DISEASE AND RENAL OUTCOMES IN PATIENTS WITH TYPE 2 DIABETES

Several large cardiovascular outcome trials, mandated by the US Food and Drug Administration to prove CVD safety for novel hypoglycemic agents, have recently shown that two classes of drugs, sodium-glucose cotransporter 2 (SGLT-2) inhibitors and glucagon-like peptide 1 receptor agonists (GLP-1 RAs), can significantly reduce the progression of CVD events and the decline in renal function in patients with type 2 diabetes.

These large-scale, randomized, placebo-controlled clinical trials have been performed in patients with type 2 diabetes and high risk of CVD (either established CVD and/or multiple risk factors for atherosclerotic disease), with the primary outcome being a composite major adverse cardiovascular event (MACE), including nonfatal myocardial infarction, nonfatal stroke, and cardiovascular death.

The first study to be published was the Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients showing that the addition of the SGLT-2 inhibitor empagliflozin to standard care induced a significant decrease in MACE (HR 0.86, $P < .001$), death from CVD (HR 0.62, $P < .001$), hospitalization for heart failure (HR 0.65, $P < .002$), and death from any causes (HR 0.68, $P < .001$).[105] These results were also replicated in the studies of canagliflozin (HR for composite primary outcome 0.86, $P < .001$), whereas dapagliflozin did not decrease MACE (HR 0.93, $P = .17$), but induced a statistically significant decreases in CVD death and hospitalization for heart failure.[106-107] The most recent SGLT-2 inhibitor, ertugliflozin, did not induce any changes in cardiovascular events.[108] These agents reduce hyperglycemia by increasing urinary glucose excretion and have also been shown to reduce renal intraglomerular pressure, and they have been evaluated for their effects on renal outcomes. These studies have been conducted in patients with type 2 diabetes and an estimated glomerular filtration rate greater than 30 mL/min/1.73 m^2 of body surface area, with a composite renal outcome including doubling of serum creatinine, initiation of renal-replacement therapy, or death from renal disease. Their efficacy in reducing renal outcomes has been demonstrated for empagliflozin (HR 0.61, $P < .001$), canagliflozin (HR 0.66, $P < .001$), and dapagliflozin (HR 0.61, $P < .001$).[109,110,111]

The first CVD outcome trial of a GLP-1 RA was published in 2015 and showed that lixisenatide did not significantly change the rate of major CVD events.[112] However, in 2016, the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results trial demonstrated that liraglutide induced a reduction in MACE (HR 0.87, $P = .01$) in patients with type 2 diabetes and high risk for CVD.[113] Similar results were observed for the GLP-1 RA semaglutide, either the subcutaneous or the oral formulations (HR 0.74, $P < .001$ and 0.79, $P < .001$, respectively),[114-115] but not for once-weekly exenatide.[116] Finally, dulaglutide was also shown to induce a significant reduction in MACE (HR 0.88, $P = 0.026$).[117] The effects of GLP-1 RA on renal outcomes has also been studied, and, although a reduction in new-onset macroalbuminuria has been demonstrated,[118] the rates of other renal adverse events were not significantly decreased with these agents. Moreover, the overall effects of GLP-1 RA on composite renal outcomes were of a much lesser degree than those observed in SGLT-2 inhibitor studies.[119] These results have changed the treatment of patients with type 2 diabetes; current guidelines now recommend that patients with type 2 diabetes and CVD use SGLT-2 inhibitors or GLP-1 RA as second agents after metformin monotherapy.[120] Specifically, patients with chronic kidney disease or congestive heart failure should preferentially add an SGLT-2 inhibitor, whereas patients with CVD or high risk for CVD should add a GLP-1 RA or an SGLT-2 inhibitor with proven CVD benefit as a second agent.[120]

KEY POINTS

- Several sodium-glucose cotransporter 2 (SGLT-2) inhibitors and glucagon-like peptide 1 receptor agonists (GLP-1 RAs) have been demonstrated to reduce cardiovascular events in patients with type 2 diabetes who are at high risk for cardiovascular disease.
- SGLT-2 inhibitors are particularly effective at reducing hospitalizations in patients with congestive heart failure.
- SGLT-2 inhibitors have also been shown to reduce composite renal outcomes, while GLP-1 RAs have shown reduction of new-onset macroalbuminuria.
- Current guidelines recommend that patients with type 2 diabetes and cardiovascular disease use SGLT-2 inhibitors or GLP-1 RAs as second agents after metformin monotherapy.

CONCLUSION

It has been clearly demonstrated that hyperglycemia affects the microvasculature through several different biochemical mechanisms and is the major cause of microvascular disease in diabetes. While several drugs have been helpful in preventing or reducing microvascular disease in animal models of diabetes, the results of clinical trials in diabetic patients have been disappointing so far. Near-normoglycemia, especially from close to the onset of type 1 or type 2 diabetes, is very effective in preventing or delaying the development of diabetic retinopathy, nephropathy, and neuropathy, and is the mainstay of current diabetes management. The increased prevalence of CVD in diabetic patient is likely the result of a combined effect of the metabolic abnormalities associated with the metabolic syndrome (i.e., obesity, hypertension, hyperlipidemia, and hyperglycemia). Conversely, focusing on the management of hyperglycemia alone is not a successful strategy in the management of the cardiovascular complications of diabetes. New hypoglycemic agents such as SGLT-2 inhibitors and GLP-1 RAs have been shown to be effective in the secondary prevention of CVD events in patients with type 2 diabetes and have been incorporated in the standard of care for such patients. Current guidelines in the management of diabetic patients focus on risk-factor control in a similar way to the Steno type 2 trial approach, and recent data have shown the efficacy of this approach. Over the last 10 years, the proportion of diabetic subjects achieving HbA1c, blood pressure, and LDL cholesterol goals has increased, even though almost half of US adults with diabetes are still not reaching the recommended goals.[121] More importantly, and at least partially as a consequence of these changes, over the last 20 years there has been a significant decline in the incidence of diabetes-related complications in the United States, with the greatest changes in myocardial infarction and death from hyperglycemic crisis (relative decreases of 68% and 64%, respectively), strokes and lower extremity amputations (decreases of 53% and 51%, respectively), and end-stage renal disease (decrease of 28%)[122] (Fig. 42.6).

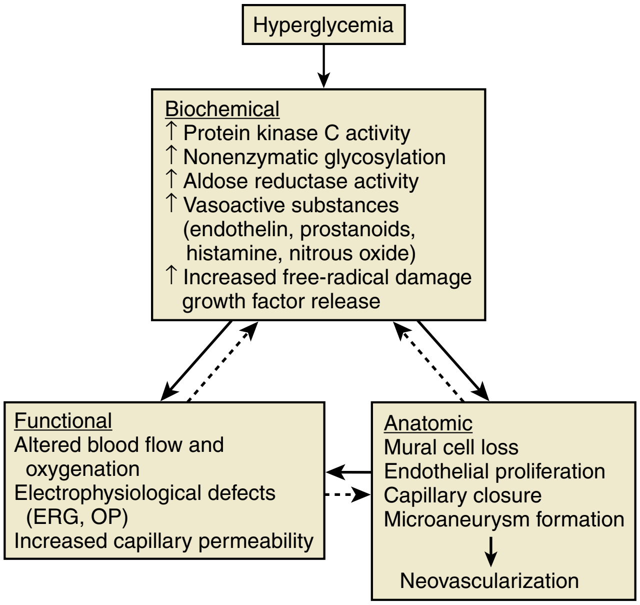
Diabetes mellitus affects virtually all structures of the eye and many aspects of visual function. Diabetic retinopathy (DR) remains an important cause of new-onset blindness in the United States and other industrialized nations.[1] Additionally, coexisting morbidities of diabetes, including hypertension, renal disease, and dyslipidemia, are associated risk factors for the progression of DR. Multicenter clinical trials have demonstrated the efficacy of glycemic and blood pressure control in reducing the risk for onset and progression of DR[2-4] and have demonstrated the effectiveness of laser photocoagulation in preserving vision and reducing the risk of vision loss.[5,6] Laser photocoagulation, however, is usually reserved for vision-threatening DR, and although laser photocoagulation significantly reduces the risk for severe visual loss (SVL) in most patients, it often does not restore vision, and it may be associated with side effects and complications. Intravitreal injections of vascular endothelial growth factor (VEGF) inhibitors have been shown to reduce the risk for moderate visual loss and improve vision in patients with diabetic macular edema (DME), but this treatment typically requires multiple repeated injections over an extended period of time, especially over the first year of treatment. Currently, laser photocoagulation and intravitreal injections are the only ophthalmic interventions proven to reduce the risk for visual loss once vision-threatening retinopathy is present; as a significant number of individuals with diabetes at risk for visual loss from vision-threatening retinopathy do not receive necessary eye care, public health efforts need to be directed at earlier detection and timely intervention.[7-11] The purpose of this chapter is to present current understanding of the pathogenesis, natural history, epidemiology, detection, and management of DR.

PATHOGENESIS

KEY POINTS

- Elevated blood glucose levels result in anatomic, functional, and biochemical changes that alter cellular metabolism, retinal blood flow, and retinal capillary permeability.

The pathogenesis of DR is not fully understood; however, many mechanisms have been suggested and are summarized in Fig. 43.1.[12-15] The development and progression of DR probably result from a complex interplay of these and other factors, which may vary from person to person. It is likely that the relative contributions of different mechanisms vary in importance at different stages of retinopathy. Glycosylation, protein kinase C, and polyol pathways and changes in retinal blood flow may be particularly important early in the course of the disease, even before the development of microaneurysms or other clinically evident findings. Angiogenesis factors such as VEGF and insulin-like growth factor-1 are more likely to be important later in the course of the disease, just before and during the development of proliferative diabetic retinopathy (PDR) or DME. In addition, interindividual and intraindividual variations in biochemical or physiologic responses to hyperglycemia (perhaps as a result of differences in genetic susceptibility) may exist among people at different stages of diabetic disease. This variability may explain why a few diabetic patients have minimal retinopathy despite years of severe hyperglycemia, whereas in others severe retinopathy develops in a short period despite relatively good glycemic control. Furthermore, these pathogenetic factors have not often been studied together in a prospective fashion, making it difficult to prove a causal relationship.



Hyperglycemia
Biochemical
↑ Protein kinase C activity
↑ Nonenzymatic glycosylation
↑ Aldose reductase activity
↑ Vasoactive substances (endothelin, prostanoids, histamine, nitrous oxide)
↑ Increased free-radical damage growth factor release
Functional
Altered blood flow and oxygenation
Electrophysiological defects (ERG, OP)
Increased capillary permeability
Anatomic
Mural cell loss
Endothelial proliferation
Capillary closure
Microaneurysm formation
Neovascularization

Fig. 43.1 **Hypothesized pathogenetic mechanisms for the development and progression of diabetic retinopathy.** *ERP,* Electroretinography; *OP,* oscillatory potentials.

NATURAL HISTORY OF DIABETIC RETINOPATHY

KEY POINTS

- Diabetic retinopathy can be broadly classified into nonproliferative diabetic retinopathy and proliferative diabetic retinopathy. Based on the presence and degree of retinal lesions, nonproliferative diabetic retinopathy is clinically classified as mild, moderate, severe, or very severe. Proliferative diabetic retinopathy is marked by proliferation of new vessels on the optic disc, new vessels elsewhere on the retina, preretinal hemorrhage, vitreous hemorrhage, or fibrous tissue proliferation. Diabetic macular edema, consisting of fluid and swelling in the central macula region, can be present with any level of diabetic retinopathy.
- Proper diagnosis of diabetic retinopathy severity establishes the risk of progression to sight-threatening retinopathy and appropriate clinical management both in terms of follow-up schedule and therapeutic options

Nonproliferative Diabetic Retinopathy

The earliest diabetes-induced changes in the retina are biochemical, hemodynamic, and cellular in nature and are imperceptible clinically. These include changes in biochemical pathways, enzyme activation, retinal blood flow, as well as cellular loss, particularly that of pericytes. The first clinical signs of DR are *microaneurysms,* which are saccular outpouchings of retinal capillaries.[16] These lesions usually appear as round red dots ranging in size from 20 to 200 μm and represent an outpouching of the retinal capillaries. They often appear first in the macular area in areas of capillary closure. It is unusual to detect retinal microaneurysms within 3 years of the diagnosis of type 1 diabetes mellitus (T1DM); however, they are often present at the time of diagnosis in people with type 2 diabetes mellitus (T2DM).[17] In the United Kingdom Prospective Diabetes Study (UKPDS), in which subjects were enrolled at the time of diagnosis of T2DM, nearly 40% of the enrollees had some level of DR at entrance into the study.[18] Moreover, after 10 years of diabetes, 69% of people with T1DM and 55% of people with T2DM have microaneurysms present.[19,20]

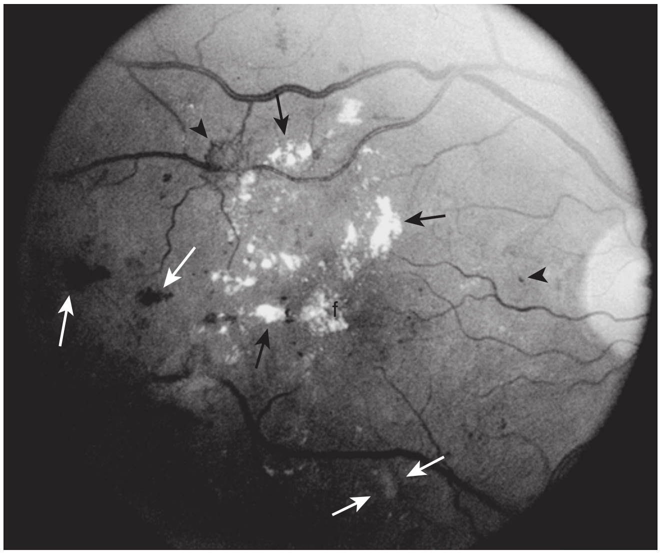


Fig. 43.2 **Fundus photograph of the right eye.** A number of retinal microaneurysms (*small black arrowheads*) appear as small dark spots with sharp margins, and retinal blot hemorrhages (*large white arrows*) appear as dark spots of varying size with irregular margins and uneven densities. Retinal hard exudates appear as white deposits with sharp margins either scattered, "ringlike," or aggregated in their distributions (*small black arrows*) in the superior, temporal, and foveal (*f*) areas. A cotton-wool spot or soft exudate (*small white arrows*) appears as a grayish white area with ill-defined edges. A retinal new vessel superior and temporal to the fovea (*larger black arrowhead*) originates from a small retinal venule.

Retinal microaneurysms are not pathognomonic of DR because they may also be associated with essential hypertension, retinal venous stasis caused by atherosclerotic carotid artery disease, acquired immunodeficiency syndrome, and other systemic and ocular conditions.[21] The appearance of a microaneurysm or two in only one eye of an individual with T2DM should not be regarded as specific for DR; however, when larger numbers of microaneurysms are present (four or more in an eye, or their presence in both eyes), they are more likely caused by diabetes, and the likelihood of progression to more severe nonproliferative DR (NPDR) is greater.[22]

Microaneurysms have abnormal permeability to fluorescein, red blood cells, and lipoproteins.[16] By themselves, microaneurysms are not a threat to vision; however, as the disease progresses, hard exudates (HEs) and retinal dot or blot hemorrhages appear. Dot hemorrhages are frequently indistinguishable from microaneurysms, and for the purposes of grading the severity of retinopathy they are frequently grouped with microaneurysm, being referred to as *hemorrhages and/or microaneurysms* (H/Ma). The blot hemorrhages are round with blurred edges and result from extravasation of blood from retinal capillaries or microaneurysms into the inner nuclear layer of the retina (Fig. 43.2). Retinal blot hemorrhages usually disappear within 3 to 4 months.[23] Ruptured microaneurysms, decompensated capillaries, and intraretinal microvascular abnormalities (IRMAs) can result in *intraretinal hemorrhages.* The clinical appearance of these hemorrhages reflects the retinal architecture at the level at which the hemorrhage occurs. Hemorrhages in the nerve fiber layer assume a more flame-shaped appearance, coinciding with the structure of the nerve fiber layer that runs parallel to the retinal surface. Hemorrhages deeper in the retina, where the arrangement of cells is more or less perpendicular to the surface of the retina, assume a pinpoint or dot shape.

Retinal HEs are sharply defined, yellow, and variable in size; they may be aggregated or scattered and partially or fully circinate in their distribution (see Fig. 43.2). A ring of HEs generally reflects the border of an area of retinal leakage. HEs result from leakage of lipoprotein material from retinal microaneurysms or capillaries into the outer retinal layer, and they may persist for months to years.[23] The exudate is usually found in the posterior layer of the retina, and if they extend into the foveal area, they may reduce visual acuity.

With closure of the retinal capillaries and arterioles, whitish or grayish swellings appear in the nerve fiber layer of the retina. These changes, termed *cotton-wool spots* (CWSs) or *soft exudates,* arise from microinfarcts in the nerve fiber layer (see Fig. 43.2). CWSs may remain only a few weeks to months. After they disappear, the retina may appear normal on ophthalmoscopy, but fluorescein angiography reveals a corresponding area of nonperfusion of the retinal arterioles.

Dilated capillaries called IRMAs are another manifestation of focal retinal ischemia. They are found in areas of capillary nonperfusion and may be abnormally permeable to plasma proteins. IRMAs represent either new vessel growth within the retina or preexisting vessels that have developed abnormal morphology, thought to include endothelial cell proliferation. IRMAs may be seen adjacent to CWSs. Multiple IRMAs identify a severe stage of NPDR.

Venous caliber abnormalities (VCABs) are indicators of severe retinal hypoxia. These abnormalities can take the form of venous dilatation, beading, reduplication, or loop formation. There are often large areas of nonperfusion adjacent to these abnormalities. Treatment with scatter (panretinal) photocoagulation (PRP) may cause these abnormal veins to become less dilated and more regular. IRMAs, intraretinal hemorrhages, and venous beading represent significant retinal ischemia. These changes were referred to as *preproliferative retinopathy* under previous classification systems and are clearly associated with more severe stages of NPDR, being a warning sign of impending retinal neovascularization. Late in the course of the disease, thinly sheathed sclerotic "white, threadlike" arterioles may be present.

Proliferative Diabetic Retinopathy

Proliferative DR (PDR) is characterized by proliferating retinal vessels, the growth of which is variable. They are commonly identified according to their retinal location: at or near the optic disc (*neovascularization of the disc* [NVD]; Fig. 43.3) or elsewhere in the retina (*neovascularization elsewhere* [NVE]; see Fig. 43.2). Retinal neovascularization may be difficult to detect when the vessels first appear as fine tufts of "naked" vessels on the surface of the retina or optic nerve head.[24] They are prone to proliferating on the posterior surface of the vitreous and hemorrhaging into the vitreous. With time, new vessels often fibrose and may contract, resulting in traction detachment of the retina. Regression of new vessels occurs as a result of photocoagulation, treatment with VEGF inhibitors, or the natural course of the disease, although fibrous tissue proliferations (FPs) typically remain.

PDR poses a significant risk for vision loss. Patients with *high-risk PDR* generally require prompt PRP. High-risk PDR is characterized by one or more of the following lesions: (1) NVD that is approximately one-quarter to one-third the disc area or more in size (i.e., greater than or equal to NVD in Early Treatment Diabetic Retinopathy Study (ETDRS) standard photograph 10A); (2) any amount of NVD if fresh vitreous or preretinal hemorrhage (PRH) is present; or (3) NVE greater than or equal to one-half the disc area in size if fresh vitreous or PRH is present. Therefore, attention must be paid to the presence, location, and severity of new vessels, as well as the presence or absence of preretinal or vitreous hemorrhages (VHs).[25]

Diabetic Macular Edema, Ischemia, and Traction

Diabetes affects the macula in a number of ways. First, increased permeability of retinal capillaries and microaneurysms may result in the accumulation of extracellular fluid and thickening of the normally compact macular tissue, with or without the development of cystoid spaces. Macular evaluation requires stereoscopic examination with slit-lamp biomicroscope, stereoscopic fundus photography, and/or optical coherence tomography. The edema may be easily missed, especially if not evaluated with appropriate equipment and by an experienced examiner. The edema is often associated with HE distributed in rings, clumps, or large deposits. Accumulation of exudate is often gradual, and spontaneous resolution may occur. Involvement of the foveal area can be associated with a profound drop in visual acuity.

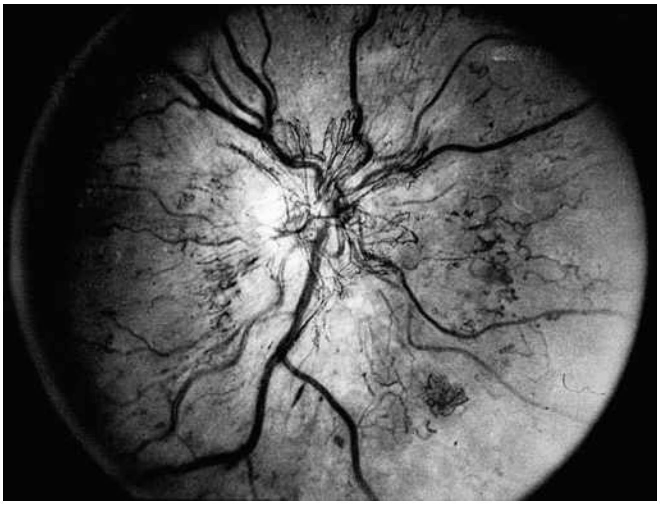

Fig. 43.3 Fundus photograph demonstrating new retinal vessels on the optic nerve head. The retinal veins are also dilated.

When macular edema threatens or involves the center of the macula, the edema is labelled clinically significant macular edema (CSME). CSME can be present with any level of NPDR or PDR, but is increasingly more common with more severe DR. The ETDRS found that CSME is associated with a 30% risk of visual loss over a 3- to 5-year period if left untreated with focal photocoagulation. This risk is reduced by 50% or more with appropriate focal laser photocoagulation.[6] CSME is defined as the presence of any of the following: (1) thickening of the retina at or within 500 µm of the center of the macula, (2) HE at or within 500 µm of the center of the macula with thickening of the adjacent retina, or (3) a zone or zones of retinal thickening one disc area or larger in size, any part of which is within one disc diameter of the center of the macula (see Fig. 43.2). The vast majority of vision loss occurs only once macular edema involves the center of the macula. The presence or absence of center-involved macular edema was the primary factor in determining short- and long-term visual acuity outcomes in the ETDRS. The current standard for DME evaluation is more focused on determining the presence or absence of edema involving the center of the macula. If center involvement of the macula is identified along with reduced vision, a regimen of intravitreal injections of VEGF inhibitors are recommended, which can reduce the risk for moderate visual loss to less than 5% and can significantly improve vision in nearly 50% of eyes when managed appropriately.

The underlying cause of macular edema is not known. It may be a result of both increased leakage and impaired removal of fluid. Breakdown of the blood-retinal barrier has been postulated as an important cause of fluid accumulation in the macula.[16] Reduced osmotic pressure resulting from decreased serum albumin levels, increased intravascular fluid load, increased arterial perfusion pressure, and tissue hypoxia have been postulated to lead to breakdown of the blood-retinal barrier. The retinal pigment epithelium normally serves to "pump" fluid out of the sensory retina, and this function is postulated to be impaired in persons with hyperglycemia. Key growth factors involved in the progression of DR, such as VEGF, have been shown to be potent permeability factors, and contribute significantly to this problem.[26,27] Clinical trials have shown that intravitreal injections of agents that inhibit VEGF rapidly induce the regression of retinal neovascularization[28] and ameliorate macular edema.[29-31]

In addition to macular edema, diabetes may cause macular capillary nonperfusion, retinal hemorrhage or PRH, lamellar or full-thickness hole formation, or dragging or detachment of the macula caused by contraction of fibrovascular tissue. These changes may occur in isolation or in combination and generally result in the loss of central vision if the fovea is involved.

CLINICAL CLASSIFICATION OF DIABETIC RETINOPATHY SEVERITY

DRs can be broadly classified as NPDR or PDR. NPDR lesions include H/Ma, dot and blot hemorrhages, CWS, HE, VCAB, and IRMA. Based on the presence and degree of retinal lesions, NPDR is clinically classified as mild, moderate, severe, or very severe NPDR. PDR is marked by ocular neovascularization as manifested by NVD, NVE, or new vessels on the iris and anterior segment of the eye, PRH, VH, or FP. DME can be present with any level of DR. DME that involves or threatens the center of the macula is classified as CSME. The involvement of the center of the macula has been associated with a significantly increased risk for visual loss. Accurate diagnosis of the severity of DR is essential because the risk for progression to PDR and high-risk PDR is closely correlated with each specific NPDR level. Proper diagnosis of DR severity establishes the risk for progression to sight-threatening retinopathy and appropriate clinical management both in terms of follow-up schedule and therapeutic options. For example, it is important to consider treatment as DR reaches severe NPDR, early PDR, or high-risk PDR.

Nonproliferative Diabetic Retinopathy Levels

Mild NPDR is marked by at least one retinal microaneurysm, but H/Ma are less than those in ETDRS standard photograph No. 2A, and no other retinal lesion or abnormality associated with diabetes mellitus is present. Those with mild NPDR have a 5% risk for progression to PDR within 1 year and a 15% risk for progression to high-risk PDR within 5 years.[32,33] *Moderate NPDR* is characterized by H/Ma greater than those pictured in ETDRS standard photograph No. 2A. Soft exudates, venous beading, and IRMA are definitely present to a mild degree. The risk for progression to PDR within 1 year is 12% to 27%, and the risk for progression to high-risk PDR within 5 years is 33%. These risks are based on estimates from a clinical trial done in the 1980s, the ETDRS, and may be lower now based on changes in management of diabetes resulting in generally improved glycemic and blood pressure control.[34] Patients with mild or moderate NPDR generally are not candidates for PRP and can be followed safely at 6- to 12-month intervals. The presence of macular edema, even with mild or moderate degrees of NPDR, requires follow-up in a shorter period. If CSME that does not involve the center of the macula is present, focal laser treatment is to be considered, and if the DME involves the center of the macula, a regimen of intravitreal injections of VEGF inhibitors is recommended, particularly when vision is also adversely affected. Coincident medical problems or pregnancy will reduce the period until reevaluation. *Severe NPDR,* based on the severity of H/Ma, IRMA, and venous beading, is characterized by any one of the following lesions: (1) H/Ma greater than standard photograph No. 2A in **four** quadrants *or* (2) venous beading in **two** or more quadrants *or* (3) IRMA greater than standard photograph No. 8A in at least **one** quadrant. Clinically, severe NPDR is diagnosed by applying the "4-2-1 rule," reflected in the definition provided earlier. Eyes with severe NPDR have a 52% risk for developing PDR within 1 year and a 60% risk for developing high-risk PDR within 5 years. These patients require follow-up evaluation in 2 to 4 months. Treatment of CSME is strongly indicated in these patients because of the high risk for the development of PDR requiring PRP.

Eyes with *very severe NPDR* have two or more characteristics of severe NPDR but no frank neovascularization. There is a 75% risk for developing PDR within 1 year. Patients with very severe NPDR may be candidates for PRP, and macular edema, if present, generally should be treated. Follow-up evaluation at 2- to 3-month intervals is important. For patients with T2DM, early PRP may be considered for patients with severe or very severe NPDR.[35]

Proliferative Diabetic Retinopathy Levels

DR with new vessel growth on the optic disc or elsewhere on the retina or with FP is designated PDR. *Early PDR* does not meet the definition of high-risk PDR. Eyes with early PDR have a 75% risk for developing high-risk PDR within 5 years. Patients with *severe* or *very severe NPDR,* or *early PDR,* may be considered for early PRP. In the presence of macular edema, patients with severe NPDR or worse DR should be considered for early focal treatment of macular edema or with intravitreal injections of anti-VEGF agents if the edema involves the center of the macula (especially when vision is reduced) in preparation for the probable need of scatter laser photocoagulation.

The ETDRS severity scale was based on the modified Airlie House classification of DR and is a recognized standard for grading severity of DR. Its use in everyday clinical practice, however, poses difficulty, both in its complexity and difficulty because definitions of the levels are detailed, require comparison with standard photographs, and are complex to remember and apply in a clinical setting. A DR severity scale was developed by the Global Diabetic Retinopathy Group at the International Congress of Ophthalmology in Sydney in April 2002.[36]

This International Classification scale defines five levels of DR. The first level is "no apparent retinopathy," and the second level is "mild NPDR," corresponding to ETDRS stage 20 (microaneurysms only). The risk for significant progression over several years is very low in both groups. The third level, "moderate NPDR," includes eyes with ETDRS levels 35 to 47, and the risk for progression increases

TABLE 43.1 International Clinical Diabetic Retinopathy Disease Severity Scale

Diabetic Retinopathy Severity	Findings Present on Ophthalmoscopy
No apparent DR	No abnormalities
Mild NPDR	Microaneurysm only
Moderate NPDR	More than microaneurysms only, but less than severe NPDR
Severe NPDR	Any of the following with no PDR: • >20 intraretinal hemorrhages in each four quadrants • definite VB in two or more quadrants • prominent IRMA in one or more quadrants
PDR	One or more of: • NV • VH • PRH

DR, Diabetic retinopathy; *IRMA,* intraretinal microvascular abnormalities; *NPDR,* nonproliferative diabetic retinopathy; *NV,* neovascularization; *PDR,* proliferative diabetic retinopathy; *PRH,* preretinal hemorrhage; *VB,* venous beading; *VH,* vitreous hemorrhage.

(From Adamis AP, Miller JW, Bernal MT, et al. Increased vascular endothelial growth factor levels in the vitreous of eyes with proliferative diabetic retinopathy. *Am J Ophthalmol* 1994;118:445–450.)

significantly by level 47. Still, the fourth level, "severe NPDR" (ETDRS stage 53), carries with it the most ominous prognosis for progression to PDR. The fifth level, "PDR," includes all eyes with definite neovascularization or vitreous hemorrhage/PRH (Table 43.1). There was no attempt to subdivide this level as a function of ETDRS "high-risk characteristics," because significant rates of progression are expected to occur in all cases.

The International Classification DME severity scale separates eyes with apparent DME from those with no apparent thickening or lipid in the macula. For eyes with apparent DME, three categories classify DME as not threatening the center of the macula (mild), threatening the center of the macula (moderate), or involving the center of the macula (severe). The clinical disease severity scale is intended to be a practical and valid method of grading severity of DR and DME (Table 43.2).

TABLE 43.2 International Clinical Diabetic Macular Edema Disease Severity Scale

Diabetic Macular Edema Disease Severity	Findings on Ophthalmoscopy
DME apparently absent	No apparent retinal thickening or HE in the posterior pole
DME apparently present	Some apparent retinal thickening or HE in the posterior pole
Mild DME	Some retinal thickening or HE in the posterior pole but distant from the center of the macula
Moderate DME	Retinal thickening or HE approaching the center of the macula but not involving the center
Severe DME	Retinal thickening or HE involving the center of the macula

DME, Diabetic macular edema; *HE,* hard exudates.
(From Adamis AP, Miller JW, Bernal MT, et al. Increased vascular endothelial growth factor levels in the vitreous of eyes with proliferative diabetic retinopathy. *Am J Ophthalmol* 1994;118:445–450.)

EPIDEMIOLOGY

KEY POINTS

- Diabetic retinopathy and diabetic macular edema affect individuals with both type 1 and type 2 diabetes.
- Type 1 diabetic patients, because of the earlier onset and longer duration of diabetes, experience more frequent and severe ocular complications. After 5 years of diabetes, 23% of type 1 diabetic patients have diabetic retinopathy. After 10 and 15 years, this prevalence increases to almost 60 and 80%, respectively. Proliferative diabetic retinopathy, the most sight-threatening stage of the disease, is present in 25 and 56% of patients with type 1 diabetes after 15 and 20 years, respectively, and often remains asymptomatic until it has progressed substantially beyond the optimal stage for initiating treatment.
- In type 2 diabetes, diabetic retinopathy was present in 20% of cases at diagnosis, increasing to 60–85% after 15 years, as assessed by the Wisconsin Epidemiologic Study of Diabetic Retinopathy. Proliferative diabetic retinopathy was present in 3–4% of patients within 4 years, 5–20% of patients after 15 years, and >50% after 20 years. Thus, patients with type 2 diabetes are more likely to have diabetic retinopathy at diagnosis and are more likely to develop diabetic retinopathy sooner after diagnosis than patients with type 1 diabetes.

Epidemiologic studies of DR are useful in developing public health strategies to prevent or reduce the occurrence or progression of this complication. In addition, epidemiologic data concerning DR, visual loss, and associated risk factors may be used in projecting costs, developing etiologic insight, designing future studies such as controlled clinical trials of treatment or prevention, and estimating the need for rehabilitative services.

One epidemiologic study that has provided data on DR, visual loss, and associated risk factors is the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR). This population-based study has been described in detail.[14,16,22,23] Data from other epidemiologic studies are also cited. Standardized examination protocols and questionnaires, photographic documentation, photographic standards for grading the severity of retinal lesions, and standardized retinopathy severity scales have permitted, in some cases, comparisons among studies.[37,38]

Prevalence and Incidence of Retinopathy

The prevalence of DR and CSME by age, gender, and diabetes group in the WESDR is presented in Table 43.3. The highest frequencies of DR and PDR were found in the younger-onset group using insulin; the lowest frequencies were in the older-onset group not using insulin. CSME was most frequent in the younger-onset group using insulin. The prevalence of DR has been reported in other selected population-based studies.[37-58] Pooled data from eight studies, including the WESDR, estimate that, among individuals 40 years of age and older, the prevalence of DR was 40%, and the prevalence of severe retinopathy (severe–very severe NPDR and PDR or macular edema) was 8%. Projection of these rates to the diabetic population 40 years of age or older in the United States resulted in an estimate of 4 million persons with DR, of whom 900,000 have signs of vision-threatening retinopathy.[1]

In the WESDR, the highest incidence and rate of progression of DR were found in the younger-onset group using insulin; the lowest incidence and rate of progression were found in the older-onset group not using insulin.[59,60] Based on the WESDR data, it is estimated that approximately 63,000 new cases of PDR occur annually nationwide, with 29,000 having PDR with DRS high-risk characteristics. In addition, approximately 50,000 new cases of DME occur each year in the United States. It should be noted that the burden of these severe complications cited at that time may currently be different owing to the increasing frequency of T2DM and decreasing incidence of PDR and CSME.[61,62] In the WESDR, this decreasing incidence of PDR and CSME is reflected in the markedly lower estimated annual incidence of any visual impairment in the most recent period of the study over a 25-year time frame.[63]

Risk Factors for Diabetic Retinopathy

Gender, Race, Genetics, and Age. Few differences are found in the risk for development and progression of DR in men and women with diabetes. However, differences among race/ethnic groups have been reported. Results from the study of Pima Indians with T2DM suggest that they are at increased risk for PDR in comparison to White Americans with T2DM.[57] After adjusting for all confounding risk factors, diabetic Mexican-Americans in San Antonio had a 2.4 times higher frequency of DR than diabetic non-Hispanic White Americans studied in the WESDR.[37] Similarly, Mexican Americans with T2DM participating in the National Health and Nutrition Examination Survey III (NHANES had an 84% higher frequency of DR than non-Hispanic White Americans.[58] The higher frequency of DR in Mexican Americans than White Americans remained after adjusting for the duration of diabetes, glycated hemoglobin (HbA1c) level, insulin and oral agent use, and hypertension in that study. However, Hamman and colleagues failed to find a difference in the frequency of DR between Hispanics and non-Hispanic White Americans examined in the San Luis Valley study.[38] West and associates also reported a similar prevalence of retinopathy in Mexican Americans with T2DM living in Arizona, of whom 48% had any retinopathy, 6% had PDR and 5% had CSME.[43] However, a higher prevalence of PDR and macular edema was found in Mexican Americans living in Los Angeles than in White Americans living in Beaver Dam.[64] In the 4-year follow-up, Mexican Americans with T2DM participating in the Los Angeles study had significantly higher annual incidence of PDR, CSME, and visual loss than reported in population-based studies of non-Hispanic White Americans.[65] It has been suggested that Black Americans with T2DM may have more severe DR and loss of vision than White Americans with T2DM.[66] In the NHANES the prevalence of DR in individuals with T2DM was 46% higher in non-Hispanic Black Americans than in non-Hispanic White Americans.[58] However, after adjustment for HbA1c, the duration of diabetes, insulin and oral agent use, and hypertension, the rates for DR were similar between White and Black Americans in that study.

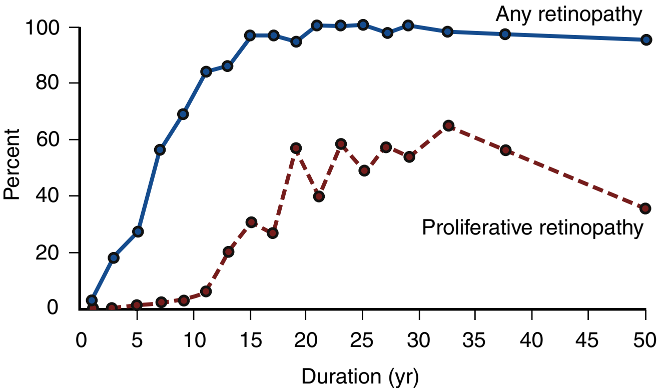

Fig. 43.4 Frequency of retinopathy or proliferative retinopathy by duration of diabetes (years) in 996 insulin-taking individuals in whom diabetes was diagnosed when younger than 30 years of age and who participated in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1982. (From Klein R, Klein BE, Moss SE, et al. The Wisconsin Epidemiologic Study of Diabetic Retinopathy. II. Prevalence and risk of diabetic retinopathy when age at diagnosis is less than 30 years. *Arch Ophthalmol.* 1984;102:520–526.)

Reports of a relationship between genetic factors and the prevalence of DR have been inconsistent.[35,67-70] Supporting such a relationship has been the observation that the severity and onset of DR are similar among concordant identical twins, which suggests that the tendency for the development of DR and possibly its progression are influenced by genetic factors.[71] In addition, Hanis demonstrated an 8.3-fold increased risk for DR in 46 Mexican American siblings of probands who had DR compared with the siblings of those who did not.[72] A high degree of familial aggregation and concordance in the development of PDR and end-stage renal disease in diabetic patients implies that common genetic factors may be important in susceptibility or resistance to these complications.[73] Case-control studies have examined other various candidate gene single nucleotide polymorphisms (SNPs) and suggested that chromosome locus 7q21 is a modifier for the risk for nephropathy in diabetes.[74-77] A specific SNP has been identified in the promoter of the erythropoietin gene, which is located at 7q21, that is associated with higher rates of development of severe diabetic eye and kidney complications.[78]

It is uncommon to find clinical evidence of DR in children younger than 10 years of age, regardless of the duration of T1DM; the frequency of any DR or more severe DR increases after 13 years of age.[79-82] This age effect has been postulated to result from a protective effect lost after the start of puberty. In the WESDR, menarchal status at the time of the baseline examination was associated with the prevalence of DR.[83] After adjusting for other factors such as diastolic blood pressure and duration of T1DM, those who were postmenarchal in the WESDR were 3.2 times more likely to have DR than those who were premenarchal.

A number of changes occurring at puberty have been thought to explain the higher risk for DR. These changes include increases in insulin-like growth factor-1, growth hormone, sex hormones, and blood pressure and poorer glycemic control. Increased insulin resistance, inadequate insulin dosage, and poorer compliance in attempts to control blood sugar may result in poorer glycemic control in postpubertal teenagers.[84-89]

Diabetes-Related Risk Factors

Multiple factors have been suggested as risk factors for onset or progression of DR. These factors include duration of diabetes,

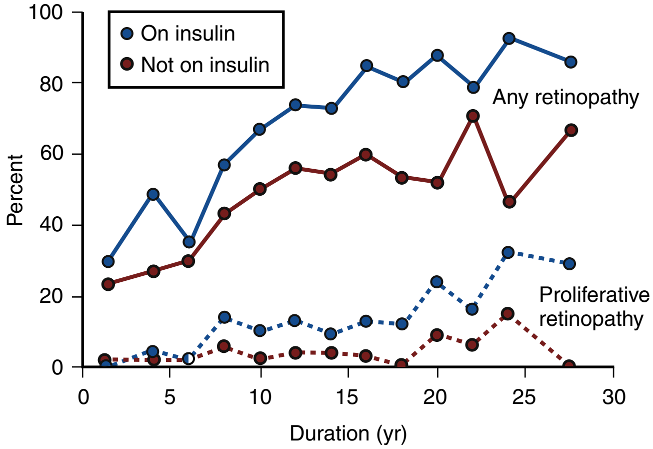

Fig. 43.5 Frequency of retinopathy or proliferative retinopathy by duration of diabetes (years) in 673 individuals taking insulin and 697 people not taking insulin in whom diabetes was diagnosed when older than 29 years of age and who participated in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1982. (From Klein R, Klein BE, Moss SE, et al. The Wisconsin Epidemiologic Study of Diabetic Retinopathy. III. Prevalence and risk of diabetic retinopathy when age at diagnosis is 30 or more years. *Arch Ophthalmol.* 1984;102:520–526.)

control of diabetes, hypertension, level of cholesterol and other lipids, renal disease, and anemia. The data associated with these risk factors have been extensively reviewed elsewhere[90] and are only presented briefly here.

Duration of Diabetes. The prevalence of DR (Fig. 43.4), macular edema, and PDR (Fig. 43.5) is significantly related to the duration of diabetes in all three diabetic groups studied in the WESDR. This observation is consistent with all previous epidemiologic studies.[39-45,47-49,55,91] The relationship between the duration of diabetes at the baseline examination and the incidence, progression of NPDR, or progression to PDR in the WESDR has been presented elsewhere.[59,60] At the time of diagnosis, DR was less common, and PDR or macular edema was not present in younger-onset diabetes, whereas the reverse was true in older-onset diabetes mellitus not taking insulin. These findings are consistent with studies that reported relatively high rates of DR at the time of diagnosis of T2DM.[92,93]

These findings have important public health implications. First, they suggest that patients with younger-onset diabetes do not need ophthalmologic evaluation for DR before puberty or before 5 years of diabetes because of the lack of vision-threatening retinopathy. For older-onset individuals, because the onset of diabetes may have been years before its diagnosis, it is important to perform a comprehensive ophthalmic examination, which includes a dilated retinal examination at diagnosis to detect possible PDR or macular edema. These findings have been used to develop guidelines recommending ophthalmologic care for patients with diabetes[94,95] (Table 43.3).

Glycemic Status. A growing body of epidemiologic data has shown that hyperglycemia is related to the incidence and progression of DR.[37,40,41,43,44,46,47,49,50,52-55,58] In the WESDR, the HbA1c level at baseline was found to be a significant predictor of the incidence of any DR, progression, incidence of PDR, or incidence of macular edema in all three diabetic groups studied.[96,97] WESDR findings and those of other studies suggest that, even in people with longer duration of diabetes, good glycemic control is more likely to be associated with lower rates

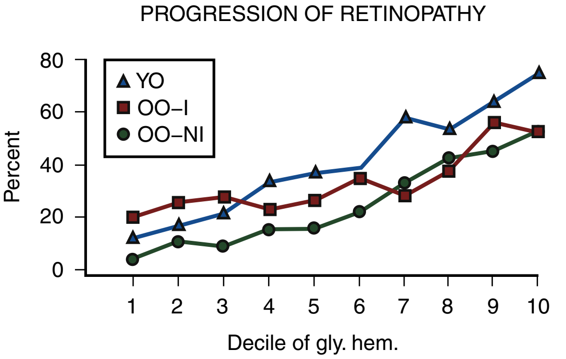

Fig. 43.6 Relationship of the 4-year progression of diabetic retinopathy to deciles of glycated hemoglobin at baseline examination in three diabetic groups participating in the Wisconsin Epidemiologic Study of Diabetic Retinopathy. *YO,* Younger onset; *OO-I,* older onset taking insulin; *OO-NI,* older onset not taking insulin.

of progression of DR than poor glycemic control.[52,97-99] In addition, in the WESDR, no threshold level of glycemia, as measured by deciles of HbA1c at baseline, was seen below which DR did not progress (Fig. 43.6).

The Diabetes Control and Complications Trial (DCCT) was a large randomized, controlled clinical trial of more than 1400 patients with T1DM[2] (see Chapter 51). This multicenter trial showed that intensive insulin treatment reduced the risk for the development and progression of DR. In that study, those assigned to intensive glycemic control had a 60% reduction in three-step or greater progression of DR than did the group assigned to conventional treatment. In the secondary intervention arm of the DCCT, those assigned to intensive glycemic control had a 34% reduction in the progression of DR, a 47% reduction in the incidence of severe levels of NPDR or PDR, a 22% reduction in the incidence of macular edema, and a 54% reduction in laser photocoagulation treatment compared with the group assigned to conventional insulin treatment. The Epidemiology of Diabetes Interventions and Complications (EDIC) study was an extension of the DCCT and followed 1395 (95%) of the 1441 original patients enrolled in the DCCT study. Participants who had been assigned to intensive treatment were encouraged to continue, and participants originally assigned to conventional treatment were advised to change to intensive treatment. The beneficial effects observed in the DCCT were sustained despite a continuously narrowing difference in HbA1c between groups that was not statistically significant by 5 years of follow-up.[99] The risk reductions observed in the DCCT between the rates of microvascular complications in the intensive treatment group compared with the conventional treatment group were sustained throughout the now 30 years of follow-up in the DCCT/EDIC cohort.[100,101]

The UKPDS was a randomized controlled clinical trial involving 3867 patients with newly diagnosed T2DM.[3] After 3 months of diet treatment, patients with a mean of two fasting plasma glucose concentrations of 6.1 to 15.0 mmol/L were randomly assigned to an intensive glycemic control group with either a sulfonylurea (chlorpropamide, glibenclamide, or glipizide) or insulin, or to a conventional glycemic control group with diet. After 10 years of follow-up, HbA1c was 7.0% in the intensive group and 7.9% in the conventional group, and the data conclusively showed that intensive treatment with either sulfonylureas or insulin significantly reduced the risk for progression of DR in individuals with T2DM.

Both the findings of the DCCT/EDIC and the UKPDS underscore the clear benefit of and need for intensive diabetes management as soon as safely possible, which should be sustained with a target HbA1c level of 7.0% or less. Although intensive therapy does not completely prevent DR, when begun early before retinal complications are present it is effective in significantly reducing the risk for development of PDR or macular edema, or the need for photocoagulation.[2,3] However, reducing glycemic control is not without adverse effects. The DCCT found a 60% risk for weight gain and a 330% increased risk for severe hypoglycemic episodes in the intensive glycemic control group versus the conventional group.[2] The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study was a randomized, controlled clinical trial that evaluated the effects of management approaches for "blood glucose levels, serum lipid levels, and blood pressure on cardiovascular events in participants with T2DM who had either established cardiovascular disease (CVD) or known cardiovascular risk factors."[102] The trial showed the efficacy of glycemic control in reducing the incidence and progression of DR. It also showed that in these patients who were at higher risk for a CVD event, intensive glycemic control treatment aimed at lowering the HbA1c level to below 6.0% was associated with a statistically significant 22% increase in mortality compared with those in the standard management group.[103] This resulted in relaxing the guidelines for treatment goals for older adults with T2DM and CVD risk factors or disease or other comorbid conditions to an HbA1c of less than 8.0% or less than 8.5%.[104]

Other Risk Factors

Blood Pressure. Clinical studies suggest a possible relationship between elevated blood pressure and the presence of DR.[85] High blood pressure, through an effect on blood flow, has been postulated to damage capillary endothelial cells, possibly contributing to the development or progression of retinopathy.[105] However, recent epidemiologic studies on the relationship of blood pressure to the incidence and progression of DR have been conflicting.[37,38,40,41,43,44,46,49,50,52,54,55,107-109] These data have been reviewed previously.[90] The UKPDS randomized 1148 patients with hypertension (mean blood pressure, 160/94 mm Hg) to a regimen of tight control with either captopril or atenolol and another 390 patients to less tight control of their blood pressure to evaluate whether tight control of blood pressure with either a β-adrenergic blocker or an angiotensin-converting enzyme inhibitor was beneficial in reducing the macrovascular and microvascular complications associated with T2DM.[4] Tight blood pressure control resulted in a 35% reduction in retinal photocoagulation compared with conventional control. After 7.5 years of follow-up, there was a 34% reduction in the rate of progression of DR by two or more steps on the modified ETDRS severity scale and a 47% reduction in moderate visual loss. The effect was largely caused by a reduction in the incidence of DME. Atenolol and captopril were equally effective in reducing the risk for development of these microvascular complications. The effects of blood pressure control were independent of those of glycemic control. These findings strongly support tight blood pressure control in people with T2DM as a means of preventing visual loss resulting from the progression of DR. However, normalization of blood pressure in the ACCORD trial (systolic blood-pressure control target to <120 vs. <140 mm Hg) showed no benefit in reducing progression of DR in individuals with T2DM and CVD or at risk for CVD.[102]

Regardless of whether blood pressure is a causal agent for the development or progression of DR, it is imperative to measure and treat high blood pressure in diabetic patients because of the known association of high blood pressure with a higher risk for heart attack, stroke, and the development of diabetic nephropathy.[110-115]

Serum Lipids. Epidemiologic data suggest a relationship between higher levels of lipids and the presence of DR or the development of HE.[38,43,49,115,116] The WESDR showed a significant trend toward increasing severity of DR and retinal HE with increasing cholesterol in the younger- and older-onset groups using insulin.[116] The ETDRS found a positive relationship between serum lipids (triglycerides, low-density lipoprotein cholesterol, and very low-density lipoprotein cholesterol) and the development of HE.[103] Although data from earlier clinical trials suggested a beneficial effect of clofibrate (Atromid-S, a lipid-lowering agent with significant hepatic toxicity) in reducing the presence of HE, it did not lead to an improvement in vision.[117,118] Results of the ACCORD-EYE study have shown that management of dyslipidemia with fenofibrate in individuals with T2DM will reduce the incidence and progression of DR.[102]

Proteinuria and Renal Disease. Diabetic nephropathy may lead to lipid, platelet, and rheologic abnormalities, all of which have been hypothesized to be pathogenetic factors for the development of DR.[119,120] Therefore, it is not surprising that most epidemiologic studies have found a strong association between the presence and severity of DR and microalbuminuria and gross proteinuria.[43,49,53,115] These relationships are independent of blood pressure.[121]

Cigarette Smoking and Alcohol Consumption. Most data from epidemiologic studies have failed to confirm earlier reports of a positive relationship between cigarette smoking and DR.[37,38,43,46,122,123] Regardless of the relationship with DR, diabetic patients should be advised to not smoke, because smoking is an important risk factor for respiratory and CVD, as well as for cancer.[124,125] Few epidemiologic studies have investigated the relationship of alcohol consumption to DR.[127-129] One might anticipate a possible protective effect of alcohol as a result of decreased platelet aggregation and adhesiveness.[129] Data from one study suggested a beneficial effect of alcohol, whereas data from another study suggested an increased risk for PDR in people with diabetes.[126,127] In the WESDR, alcohol consumption was associated with a lower frequency of PDR in the younger-onset group.[128] However, no relationship was found between alcohol consumption at the 4-year examination and the incidence and progression of DR in either the younger- or older-onset groups at the 10-year follow-up.[128]

Pregnancy. Epidemiologic studies suggest that pregnancy is a significant risk factor for progression of DR.[130] In a review of the literature, Rodman and colleagues reported that 8% of women with T1DM who had no or early NPDR at the onset of pregnancy had progression of DR during pregnancy.[131] In a case-control study of women with T1DM, the frequency of progression to PDR retinopathy was higher in those who were pregnant than in those who were not (7.3% vs. 3.7%).[130] Women in this study were similar in age, duration of diabetes, and DR status at the baseline examination. Pregnancy remained a significant risk factor for progression of DR after controlling for HbA1c. Severe DR is also an indicator of a higher risk for congenital abnormalities in children born of mothers with T1DM.[132]

Comorbidity. In the WESDR, diabetic individuals with PDR were at higher risk for the development of diabetic nephropathy, heart attack, stroke, and amputation than were those with minimal or no DR present.[121] This observation is consistent with the association of severe DR with CVD risk factors such as increased fibrinogen, increased platelet aggregation, hyperglycemia, and hypertension.[116,119,120,133,134] Retinal vessel diameters, independent of retinopathy severity levels, have also been shown to be associated with stroke, diabetic nephropathy, and lower extremity amputation.[135,136]

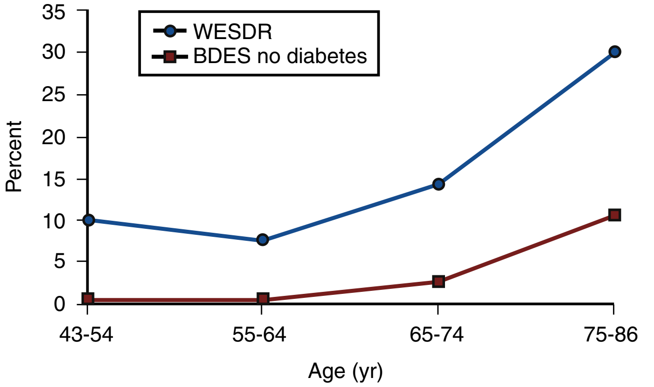

Fig. 43.7 Visual impairment (best-corrected visual acuity in the better eye of 20/40 or worse) in those with diabetes participating in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1982, and in those without diabetes participating in the Beaver Dam Eye Study, 1988–1990. *WESDR,* Wisconsin Epidemiologic Study of Diabetic Retinopathy; *BDES,* Beaver Dam Eye Study.

OTHER OCULAR DISEASES ASSOCIATED WITH DIABETES

KEY POINTS

- Diabetic eye disease affects structures of the eye that are susceptible to the deleterious effects of diabetes. The most common nonretinal ocular disease due to diabetes include the development of earlier and more rapidly progressing cataracts and a higher incidence of glaucoma.

Cataract

Cataract is an opacification of the normally clear crystalline lens of the eye. Individuals with diabetes tend to develop cataracts at a younger age, and the cataracts develop more rapidly, compared with individuals without diabetes.[137] In both the NHANES and the Framingham Eye Study, diabetic participants younger than 65 years of age had a respective 3.0 and 4.0 increased risk for having a cataract compared with similarly aged nondiabetic participants. Individuals with diabetes appear to have differences in the frequency and severity of specific lens opacities. In the Beaver Dam Eye Study, after adjusting for age and sex, cortical opacities and posterior subcapsular cataract were significantly more common among individuals with older-onset diabetes than in the rest of the Beaver Dam population.[138] In the younger-onset group in the WESDR, the prevalence of cataract surgery and cataract was significantly related to older age at examination, longer duration of diabetes, diuretic usage, higher HbA1c concentration, and more severe DR.[139] In the older-onset groups, the prevalence of cataract was associated with older age, diuretic usage, smoking, and more severe retinopathy. In the UKPDS, intensive glycemic control was associated with a significant reduction in cataract extraction compared with those with conventional control.[3]

Glaucoma

Glaucoma is usually defined by the presence of characteristic visual field loss associated with damage to the retinal nerve fiber layer as a result of intraocular pressure higher than the eye can tolerate. Diabetes has been suggested as increasing the risk for glaucoma.[140] However, neither the Framingham Eye Study nor a study in Dalby, England, found a relationship between diabetes and glaucoma.[141,142] In the WESDR, a history of glaucoma was more frequent in younger and older diabetic individuals than in the general population studied in the Health Interview Survey or in nondiabetic participants in the WESDR.[142-145] In the Beaver Dam Eye Study, after controlling for age and sex, diabetes was associated with an 84% increase in the risk for glaucoma.[141] The Nurse's Health Study, which enrolled 76,318 women who were followed from 1980 to 2000, showed that T2DM was associated with a 1.23 to 2.7 increased risk for developing primary open-angle glaucoma.[145]

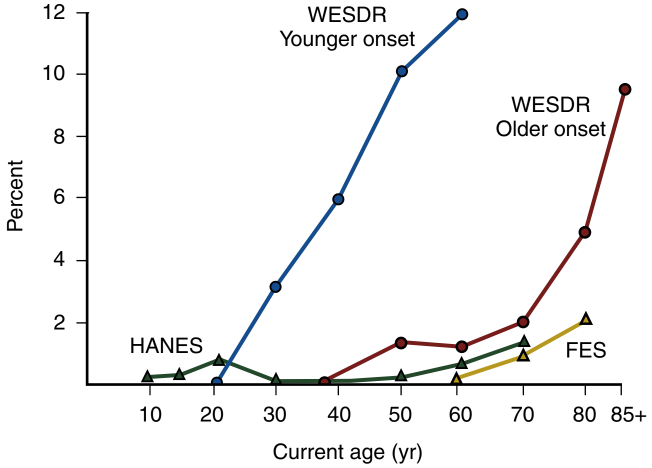

Fig. 43.8 Percentage of individuals with visual acuity of 20/200 or worse in the better eye in the Wisconsin Epidemiologic Study of Diabetic Retinopathy (*WESDR*), the National Health and Nutrition Examination Survey (*NHANES*), and the Framingham Eye Study (*FES*) by current age. (From Klein R, Klein BE, Moss SE. Visual impairment in diabetes. *Ophthalmology*. 1984;91:1–9.)

Visual Impairment

In the WESDR, individuals with diabetes had a higher age-specific prevalence of visual impairment (best-corrected visual acuity in the better eye of 20/40 or worse) than did the nondiabetic population in the Beaver Dam Eye Study (Fig. 43.7), as well as a higher age-specific prevalence of legal blindness (best-corrected visual acuity in the better eye of 20/200 or worse) than found in the general population in either the Framingham Eye Study or the NHANES[146] (Fig. 43.8). For the younger-onset group using insulin, DR was responsible for 86% of the visual loss; for the older-onset group, it was responsible for 33% of the visual loss. In the WESDR, the annual incidence of blindness caused by diabetes mellitus was estimated to be 3.3 per 100,000 general population.[147] The 4-year incidence of legal blindness was higher in the older-onset groups (3.2% in those using insulin and 2.7% in those not using insulin) than in the younger-onset group (1.5%). The incidence of visual impairment because of DR appears to be decreasing in individuals with T1DM in the WESDR.[148] However, the prevalence of visual impairment in T2DM appears to have increased from the 1999 to 2002 to the 2005 to 2008 NHANES and is thought to be attributable in part to an increase in the prevalence during this time period.[149,150]

DETECTION

KEY POINTS

- Detection of diabetic retinal complications is best achieved by ophthalmoscopic examination through a dilated pupil by a retinal specialist or an eye doctor with expertise in diabetes eye care. Alternative means for retinal evaluations include ocular telehealth programs that use validated means of retinal imaging to identify eyes at risk for visual loss. Ocular telehealth programs have the potential to preserve vision and prevent vision loss by increasing access to evaluation, educating patients, and promoting appropriate follow-up.

TABLE 43.4 Recommendations for Eye Care for Diabetic Patients

Primary care physician informs the patient at the time of diagnosis of diabetes that:
- Ocular complications are associated with diabetes and may threaten sight
- Timely detection and treatment may reduce the risk for decreased vision-Referral to an eye doctor competent in diabetes eye care:
- All patients 10–30 years of age who have had diabetes for 5 or more years
- In patients in whom diabetes was diagnosed when older than 30 years of age, examination at the time of diagnosis or shortly thereafterReferral to an ophthalmologist:
- All women with insulin-dependent diabetes mellitus planning pregnancy within 12 months, in the first trimester, and thereafter at the discretion of the ophthalmologist
- Patients found to have reduced corrected visual acuity, elevated intraocular pressure, and any other vision-threatening ocular abnormalities

Detection of DR is best achieved by ophthalmoscopic examination through a dilated pupil by a retinal specialist or an eye doctor with expertise in diabetes eye care.[95] Stereoscopic color fundus photography increases the sensitivity of detection of vision-threatening retinopathy relative to ophthalmoscopy and is especially indicated when monitoring patients with signs of NPDR, PDR, or macular edema.[152-154] Fluorescein angiography is generally used by retinal specialists before laser photocoagulation treatment of eyes with CSME to detect areas of retinal ischemia and leaking microaneurysms. Angiograms may occasionally be used to provide further information regarding the amount of ischemia and to demonstrate the cause of unexplained visual loss. However, fluorescein angiography is not routinely necessary at the time of diagnosis or in diabetic patients with no or minimal NPDR.

In the WESDR in 1980 to 1982, 33% of individuals with either PDR with a high risk for SVL or CSME had not seen an ophthalmologist within 2 years of the examination.[154] In addition, 51% of eyes with PDR had not been treated with PRP.[155] Based on these data, it is estimated that 35,000 Americans with vision-threatening DR who might benefit from photocoagulation treatment had not received such treatment in 1980 to 1982. Little change was found when the group was reexamined,[156] and similar findings have also been reported by others.[158-160] Many possible reasons have been proposed to explain the high rate of patients with serious DR who do not receive appropriate eye care.[11,24,157,161-165] Guidelines for the detection and management of diabetic eye disease have been developed and distributed[95] (Table 43.4). However, studies have suggested that these referral guidelines for DR are not being sufficiently followed.[7,158,159,164] Cost-effectiveness studies using the WESDR and other data suggest that earlier detection of PDR by ophthalmologic or photographic screening is a cost-effective approach for diabetic individuals requiring insulin.[166-168] The American Diabetes Association has recognized the value of retinal imaging in assessing DR and states that examinations can be done with retinal photographs with or without pupil dilation read by experienced experts, but that in-person exams are still necessary when photos are unacceptable and for follow-up of abnormalities detected.[168]

Telemedicine Programs for Diabetic Retinopathy

Despite multiple national and global initiatives, a significant number of individuals with diabetes mellitus who are at risk for visual loss from vision-threatening retinopathy do not receive necessary eye care.[13-15] Public health efforts need to be directed at earlier detection and providing access to appropriate levels of eye care. Ocular telehealth programs for DR have the potential to expand access to highly effective evidence-based diabetes eye care and provide cost-effective alternative methods of care.[169,170] Studies across multiple populations demonstrate that the prevalence of blindness and visual impairment among patients with diabetes is lowest among populations with a national program that provides retinal evaluations for all patients with diabetes.[172-175] The implementation of national coverage of universal retinal evaluation for all patients with diabetes has been shown to reduce the incidence of blindness by as much as 95%.[176-178] Ocular telehealth programs for DR have the potential to preserve vision and prevent vision loss by increasing access to evaluation, educating patients, and promoting appropriate follow-up and treatment.

MANAGEMENT

KEY POINTS
- Medical management relies on achieving control of blood glucose, blood pressure, and blood lipids which have been shown to greatly reduce the risk for development and progression of diabetic retinopathy and to limit visual loss in patients with diabetes.
- Nationwide, multicenter, randomized clinical trials have largely determined the appropriate strategies for ophthalmic management of patients with diabetic retinopathy. Panretinal laser photocoagulation should be considered as an eye approaches the high-risk stage of proliferative retinopathy and intravitreal injections of vascular endothelial growth factor (VEGF) inhibitors have been shown to be as effective as laser photocoagulation for treating proliferative retinopathy. When therapy is initiated at the first sign of appropriate severity of diabetic retinopathy, benefits may include a reduction of more than 90% in severe visual loss.
- Results for the Diabetic Retinopathy Clinical Research Network and pharmaceutical studies have shifted the initial therapeutic approach for patients with center-involved diabetic macular edema and visual loss to a regimen of repeated intravitreal injections of vascular endothelial growth factor (VEGF) inhibitors. These inhibitors can reduce moderate visual loss from DME to less than 5% and lead to visual improvement of 10 letters or more in more than half of these patients.

Medical

As discussed earlier in the chapter, the DCCT and UKPDS studies have demonstrated that it is important to manage glycemic and hypertension control carefully for optimum care of patients with diabetes mellitus. Achieving control of blood glucose and blood pressure has been shown to greatly reduce the risk for development and progression of DR and to limit visual loss in patients with diabetes. However, intensive glycemic control is often difficult or impossible to achieve in certain patients. Strict glycemic control is also associated with an increased frequency of severe complications.[2] An unexpected worsening of DR in the first 3 to 12 months following the initiation of intensive insulin therapy (termed "early worsening") was observed in the DCCT and several other smaller clinical trials.[179-182] In the DCCT, clinically significant early worsening (defined as a three-step progression of DR within the first 12 months) was observed in 13.1% of 711 patients assigned to intensive treatment and in 7.6% of 728 patients assigned to conventional treatment (odds ratio, 2.06; $P < .001$). In both groups, recovery occurred at the 18-month visit in 51% and 55% of patient, respectively ($P = .39$). The risk factors for early worsening were higher baseline HbA1c and greater reduction of HbA1c after enrollment. In the DCCT, early worsening did not lead to serious visual loss, but data support the conclusion that early worsening may be more common and more sight-threatening in patients with more severe retinopathy and/or very poor glycemic control. It is recommended that patients with moderate or worse NPDR should be monitored closely before and for several months after initiation of intensive insulin treatment.[178] Initiation of laser treatment should be considered when factors suggest a particular need to protect against advancing severe retinopathy, such as in patients with actively progressing DR, longstanding very poor glycemic control, and high likelihood of suboptimal follow-up.[178] Given the long-term benefits of improved glycemic control in reducing the risk for DR progression and the availability of highly effective treatment for vision-threatening DR, intensive glycemic control should generally not be discouraged for fear of DR progression.[182,183]

Ophthalmic

Several nationwide, multicenter, randomized clinical trials have largely determined the appropriate strategies for clinical management of patients with DR. The Diabetic Retinopathy Study conclusively demonstrated that PRP significantly reduces the risk for SVL from PDR, particularly when high-risk PDR was present.[5,184,185] The ETDRS provided valuable information concerning the timing of PRP for advancing DR and conclusively demonstrated that focal/grid photocoagulation for CSME reduces the risk for moderate visual loss by 50% or more.[5,32,186] Furthermore, the ETDRS demonstrated that both early PRP and deferral of PRP "until and as soon as high-risk PDR developed are effective in reducing the risk for SVL." PRP, therefore, should be considered as an eye approaches the high-risk stage and "usually should not be delayed if the eye has reached the high-risk proliferative stage."[32] Detailed analysis of the ETDRS data shows that early PRP is beneficial for patients with T2DM.[187,188] When therapy is initiated at the first sign of appropriate severity of DR, benefits may include a reduction of more than 90% in SVL.[32,188] Results for the Diabetic Retinopathy Clinical Research Network[29-31] and pharmaceutical studies[189,190] have shifted the initial therapeutic approach for patients with center-involved DME and visual loss to a regimen of repeated intravitreal injections of VEGF inhibitors. Focal/grid photocoagulation is then added secondarily as needed; however, approximately 50% of the patients will never require focal grid photocoagulation after anti-VEGF therapy. Intravitreal injections, when used according to the protocol described in these studies, can result in limiting moderate visual loss from DME to less than 5% and lead to visual improvement of 10 letters or more in more than half of these patients.

Surgical

Vitrectomy surgery has been effective in reducing vision loss when traction retinal detachment threatens the center of the macula or VH fails to clear. The use of laser delivered from within the eye at the time of surgery and other advanced surgical techniques make vitrectomy a valuable procedure to prevent vision loss and restore vision.

Neovascular glaucoma, in which retinal ischemia leads to neovascularization of the anterior chamber angle of the eye, is a severe and difficult-to-treat complication of advanced DR. Such eyes are at high risk for SVL. Aggressive PRP is usually the preferred initial treatment, but other procedures such as goniophotocoagulation of neovascularization in the filtration angle, filtration surgery, vitrectomy surgery, or combinations of these procedures may be necessary. The use of intravitreal anti-VEGF agents initially in eyes with severe neovascularization of the iris angle have dramatically improved the treatment of those cases where the severity of the condition precluded laser treatment.[191] In these cases, the use of anti-VEGF agents induce a rapid, temporary resolution of the vessels, allowing laser treatment to be subsequently performed.[192]

Rehabilitation

Diabetic patients with severe visual impairment are confronted with difficulties in glucose monitoring, insulin administration, and monitoring of systemic changes in the skin such as foot ulcers. In addition, these patients are often ill with renal disease, CVD, or amputations. Many have lost their jobs and health insurance and are without adequate financial support. These problems may lead to anger, anxiety, loss of self-esteem, and difficulties in social adjustment.[193]

Patients with reduced vision frequently benefit from referral to low-vision specialists or eye doctors specializing in vision rehabilitation. Spectacle, handheld, or stand magnifiers may be useful in near tasks such as insulin dosage, reading, computer work, job-related tasks, and hobbies. Telescopes may improve distance vision, and in some cases permit individuals with reduced vision to resume driving. A variety of electronic devices is available to enhance reading activities, and computer software is available to assist in the use of work- and leisure-related tasks.

Primary care physicians should be actively involved in a team including psychologists, orientation and mobility instructors, rehabilitation teachers, and social workers to deal with the problems faced by visually impaired diabetic patients. Such support facilitates acceptance of visual loss, development of coping strategies, and planning of living arrangements.

Protective and Risk Factors for Diabetic Retinopathy

Recent interest has focused on possible genetic risk factors that may delay or hasten the progression to severe PDR. There are published reports on two unique cohorts of T1DM patients with more than 50 years of diabetes. The Golden Years cohort has shown a possible genetically determined protective effect against the development of diabetic nephropathy and large vessel disease.[194] The 50-Year Medalist Study at Joslin Diabetes Center has demonstrated that substantial proportions of individuals may survive diabetes with a duration of 50 years or more and remain free of advanced diabetic vasculopathy, including PDR (49.4%). Longitudinal data from a subgroup of 97 Medalists followed for an average of 20.6 years and 39.4 visits suggest that retinopathy worsening occurs almost entirely within the first 2 decades of follow-up, and eyes that do not develop PDR have a slower rate of retinopathy progression. The data from these two cohorts point to a possible genetic susceptibility or protective factors against the development of PDR.[195,196] The identification of novel genes may potentially help understand the pathogenic pathways underlying DR. SNPs such as the one observed in the promoter region of the erythropoietin gene has been shown to result in the dramatic increase in expression of erythropoietin, which is a known angiogenic factor in the eye.[78] This polymorphism is associated with higher rates of development of severe diabetic eye and kidney complications and represents one of the first gene mutations specifically associated with DR.

NOVEL THERAPIES

With the emerging global epidemic of diabetes and rapid advances in scientific discovery, there has been a dramatic shift and remarkable improvements in the prevention of visual loss from diabetic retinal disease. Despite these advances, it remains critical that we continue to identify the most promising new therapies and evaluate them in as rigorous and timely a manner as possible. Collaborative efforts between eye care specialists in the highly successful National Eye Institute–sponsored Diabetic Retinopathy Clinical Research Network (www.DRCR.net) have allowed basic science discoveries to be rapidly translated into the clinical setting for the benefit of the patient. It is through collaborative efforts such as these and the close involvement of a multidisciplinary team of healthcare providers that we ultimately may be able to prevent eye and other complications of this systemic disease.

Conclusions, 767

KEY POINTS

- Early recognition and appropriate management of neuropathy in all patients with diabetes is essential to prevent serious complications.
- Diabetic neuropathy is a diagnosis of exclusion.
- Nondiabetic neuropathies mimicking diabetic neuropathy may be present in patients with diabetes and may be treatable by specific measures.
- Up to 50% of diabetic peripheral neuropathies may be asymptomatic.
- Various forms of peripheral and autonomic neuropathies have been described in patients with prediabetes/metabolic syndrome and obesity, as well as in youth.
- If not recognized, and if preventive foot care is not implemented, patients are at risk of injuries to their insensate feet.
- Several treatment options exist for painful diabetic peripheral neuropathy and some forms of autonomic neuropathy.
- Recognition and treatment of autonomic neuropathy may improve symptoms, reduce sequelae, and improve quality of life.

DEFINITION OF DIABETIC NEUROPATHIES

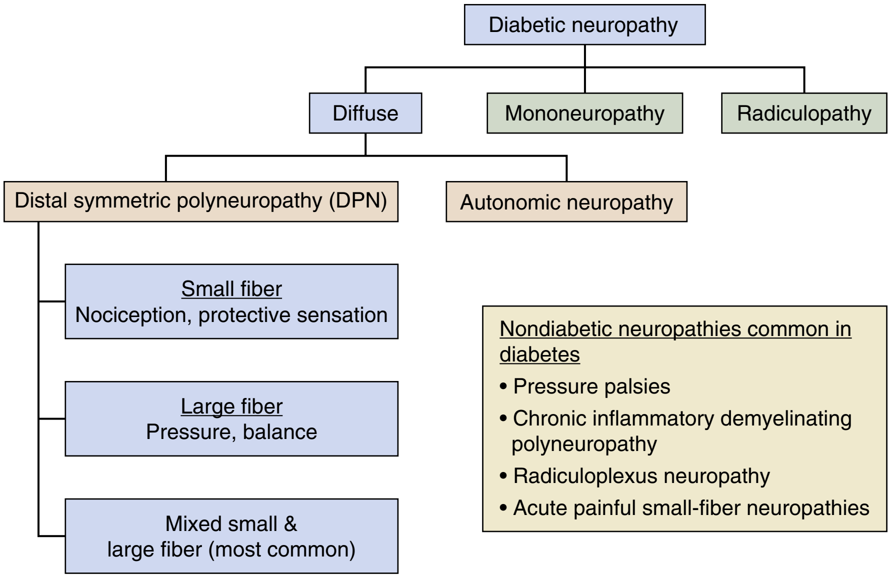
The consensus in the field is that diabetic neuropathies are defined by the presence of symptoms and/or signs of peripheral and autonomic nerve dysfunction in people with diabetes after the exclusion of other causes confirmed through a careful clinical examination and appropriate differential tests.[1,2] However, emerging evidence reports that various forms of peripheral and autonomic neuropathies similar to diabetic neuropathies have been described in patients with prediabetes/metabolic syndrome and obesity.[1,3]

CLASSIFICATION OF DIABETIC NEUROPATHIES

Among the various forms of diabetic neuropathy, distal symmetric polyneuropathy (DSPN) and diabetic autonomic neuropathies, particularly cardiovascular autonomic neuropathy (CAN), are by far the most studied.[1,4,5] There are several atypical forms of diabetic neuropathy as well.[1,6] A comprehensive classification of diabetic neuropathies has been recently updated by the American Diabetes Association (ADA) in the 2017 Statement on Diabetic Neuropathy and is shown in Fig. 44.1.[1]

Pathogenesis

Diabetic neuropathy is a unique neurodegenerative disorder of the peripheral nervous system that preferentially targets sensory axons, autonomic axons, and later, to a lesser extent, motor axons.[3] Experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy, but how diabetes targets sensory neurons remains debatable. Although diabetic neuropathy is not considered primarily a demyelinating neuropathy, Schwann cells are targeted by chronic hyperglycemia, and more severe forms of human diabetic neuropathy do include features of demyelination.[3] There is significant experimental evidence to support the idea that the entire neuronal tree, from perikarya to terminal, including alterations in sensory neurons within dorsal root ganglia, may be targeted by diabetes.[3] A prevailing view of the pathogenesis is that hyperglycemia and hyperlipidemia lead to increased flux of glucose metabolized through the polyol and hexosamine pathways, oxidative and inflammatory stress, excessive free fatty acids as well as alterations in substrate energy metabolism, mitochondrial dysfunction, and a maladaptive integrated stress response, as well as lipid oxidation and nonenzymatic glycation in the context of metabolic dysfunction, all leading to damage to nerve



Diabetic neuropathy
Diffuse
Mononeuropathy
Radiculopathy
Distal symmetric polyneuropathy (DPN)
Autonomic neuropathy
Small fiber
Nociception, protective sensation
Large fiber
Pressure, balance
Mixed small & large fiber (most common)
Nondiabetic neuropathies common in diabetes
• Pressure palsies
• Chronic inflammatory demyelinating polyneuropathy
• Radiculoplexus neuropathy
• Acute painful small-fiber neuropathies

Figure 44.1 Classification of diabetic neuropathies.

cells.[1,3] A detailed review of the intricate pathogenic mechanisms is however beyond the scope of this chapter, and the reader is referred to other comprehensive reviews.[3]

KEY POINTS

- The mechanisms leading to the development of diabetic neuropathies are intricate, involving complex interactions between hyperglycemia, hyperlipidemia, and other risk factors leading to inflammatory and oxidative stress, mitochondrial dysfunction, impaired substrate energy metabolism with disruption in whole-nerve bioenergetics, and ultimately loss of function and degeneration of small and large nerve fibers.

DISTAL SYMMETRICAL POLYNEUROPATHY

DSPN is the most common form of diabetic neuropathy, and most of the available evidence regarding the epidemiology, pathogenesis, and treatment is relevant to this form.[1,2]

Epidemiology

DSPN is the most common complication of both type 1 diabetes (T1D) and type 2 diabetes (T2D), with an estimated lifetime prevalence exceeding 50%.[1,2] Precise prevalence and incidence estimates for DSPN have been also hampered by limitations in the outcome measures selected to define DSPN in various large cohorts, as well as by a rather high heterogeneity in the diagnostic criteria. There are differences in the epidemiology and natural history of diabetes neuropathy between T1D and T2D, despite no major structural differences in nerve pathology.

As demonstrated by the Diabetes Control and Complications Trial (DCCT), arguably the largest and best phenotyped cohort of patients with T1D with comprehensive and repeated measures of DSPN, the prevalence of DSPN is quite low in patients with early T1D, at approximately 5% at baseline.[1,7] However, among DCCT participants who were considered to be nonneuropathic at baseline, the prevalence of an abnormal neurologic exam was almost 20% in those on conventional treatment and almost 10% in those on intensive treatment after approximately 5 years of follow-up.[4,7] Moreover, the prevalence of DSPN increased during observational follow-up of the DCCT cohort in the Epidemiology of Diabetes Interventions and Complications (EDIC) study, and the most recent analysis reported that, over 23 years of mean follow-up, 33% of DCCT/EDIC participants developed confirmed DSPN.[4] Beyond glycemia as defined by time-weighted hemoglobin A1c and diabetes duration, additional risk factors for development of DSPN in the DCCT/EDIC cohort were diabetic kidney disease, elevated blood pressure (BP), height, and elevated triglycerides.[4] The European Insulin-Dependent Diabetes Mellitus Prospective Complications Study (EURODIAB IDDM), a large cross-sectional cohort of randomly selected patients with T1D from 16 European countries, reported mean prevalence rates of DSPN of 28%, but with significant DSPN trends associated with age, diabetes duration, and hemoglobin A1c, as well as with hypertension and hyperlipidemia.[8] However, these earlier cohorts may not be entirely representative of contemporary populations. Thus, the most recent data from the T1D Exchange, using the validated Michigan Neuropathy Screening Instrument (MNSI) questionnaire in a large cohort of approximately 6000 T1D participants, reported a DSPN prevalence of 11% after a median of 32 years of diabetes duration.[5] Risk factors for DSPN in this cohort include traditional risk factors such as older age, longer duration of diabetes, poor glycemic control, other microvascular complications, established cardiovascular disease (CVD), and CVD risk factors including body mass index, smoking history. and high triglycerides. However, the T1D Exchange analyses also unveiled a strong association of DSPN with female gender, as well as with several socioeconomic factors that had not been described before.[5] Interestingly, very similar findings were unveiled in another contemporary T1D cohort, the Scottish T1D cohort, that used the same MNSI questionnaire to assess DSPN in approximately 6000 participants, reporting prevalence rates of approximately 13% and also confirming similar risk factors, as well as the role of socioeconomic factors.[9]

DSPN may be present in at least 10% to 15% of newly diagnosed patients with T2D, with rates increasing to 50% after 10 years of disease duration.[1] For instance, in more than 5000 T2D participants in the Glycemia Reduction Approaches in Diabetes - A Comparative Effectiveness (GRADE) trial, approximately 21% of this contemporary cohort with a mean known T2D duration of only 4 years presented with DSPN at baseline as diagnosed with the MNSI (both examination and questionnaire).[10] In a cohort of greater than 1500 individuals with screen-detected T2D participating in the ADDITION-Denmark Study, the prevalence of DSPN assessed with the MNSI questionnaire was approximately 13% at baseline, with cumulative incidence rates of 10% over 13 years of follow-up.[11] In contrast, the Bypass Angioplasty Revascularization Intervention 2 Diabetes (BARI 2D), which enrolled greater than 2300 participants with T2D with a mean diabetes duration of approximately 10 years and confirmed coronary artery disease, found that the prevalence of DSPN at baseline as assessed by MNSI was approximately 50%.[12] The rates of DSPN are higher in various ethnic groups. Recent data show, for instance, that American Indians, besides having disproportionally higher rates of T2D, also develop more chronic complications, including DSPN.[13]

In addition, emerging evidence demonstrates that DSPN rates in youth with T1D and T2D approach those observed in adult populations. The most recent report from the SEARCH study including approximately 2000 youth with T1D and T2D reported DPSN prevalence rates as high as 22% in youth with T2D.[14] There is also emerging evidence that DSPN, especially the painful small fiber neuropathy subtype, may be present in 10% to 30% of subjects with impaired glucose tolerance, prediabetes, or metabolic syndrome.[1]

KEY POINTS

- Distal symmetric polyneuropathy (DSPN) is the most common form of diabetic neuropathy.
- DSPN prevalence increases with disease duration, with an estimated lifetime prevalence of ~35% in type 1 diabetes (T1D) and exceeding 50% in type 2 diabetes (T2D).
- DSPN remains prevalent in contemporary cohorts of T1D and T2D across the world, despite changes in standards of care.
- High rates of DSPN have been reported in prediabetes and in youth.

Screening and Diagnosis in Clinical Care

DSPN involves a loss of sensory function beginning distally that is also characterized by pain and substantial morbidity.[3] It is usually of gradual onset and may be present at the diagnosis of T2D in greater than 10% of subjects.[1,2]

DSPN Symptoms: Symptoms of DSPN vary depending on the class of sensory nerve fibers involved. The earliest affected nerve fibers are usually the small myelinated and unmyelinated fibers, thus the most common early symptoms are pain and dysesthesias (unpleasant sensations of burning).[1,2] Neuropathic pain may be the first symptom that prompts patients to seek medical care and is present in up to 25% to 30% of individuals with DSPN.[1-3] Characteristically, the pain is burning, lancinating, tingling, or shooting (electric shock–like), with paresthesias, occurring in varying combinations, and is typically worse at night.[1,2] Neuropathic pain may be accompanied by an exaggerated response to painful stimuli (hyperalgesia) and pain evoked by contact, e.g., with socks, shoes, and bedclothes (allodynia).[1,2] Neuropathic pain can lead to interference with daily activities, disability, psychosocial impairment, and reduced health-related quality of life.[15-17] The direct and indirect economic burden associated with neuropathic pain is substantial.[17,18]

The involvement of large fibers may cause numbness, tingling without pain, and loss of protective sensation. Patients can also initially present with a completely insensate, numb foot, stating their feet feel like they are wrapped in wool, or they are walking on thick socks.[1,19]

DSPN Signs: There are several established clinical tests that may be easily used to assess small- and large-fiber function, as summarized in Table 44.1. In clinical care, assessment of pinprick and temperature (mostly cold) sensation provides reliable information on small-fiber function, while assessment of vibration perception (with a 128-Hz tuning fork), proprioception, light touch to a 10-g monofilament, and ankle reflexes allow assessments of large-fiber function,[1] all in a "stocking and glove" distribution. Pinprick is tested using a sharp object, such as a safety pin, that is discarded after each patient, temperature is tested by application of a cool material such as a metallic object, and proprioception is examined by small movements of the distal interphalangeal joint of the great toe.[1,3] Assessment of light touch perception using a 10-g monofilament should be performed on the dorsal aspect of the great toe bilaterally.[1] However, it is important to consider that the 10-g monofilament is a useful clinical tool mainly for detecting advanced neuropathy and identifying patients at increased risk of ulceration and amputation.[1,2] Loss of ankle reflexes occurs early, and later weakness of small foot muscles and dorsiflexors is also observed.[1,3]

TABLE 44.1 Clinical Symptoms and Signs of DSPN

	Large Myelinated Nerve Fibers	Small Nerve Fibers
Function	Pressure, balance	Nociception; protective sensation
Symptoms	Numbness Tingling Poor balance	Pain: Burning Electric shocks Stabbing pain
Examination (clinically diagnostic)**	Ankle reflexes Reduced Abolished Vibration perception* Reduced Absent 10-g monofilament* Reduced Absent Proprioception impaired	Thermal (cold/hot) discrimination* Reduced Absent Pinprick sensation* Reduced Absent

*Documented impairment/loss of symmetry, as well as a distal to proximal pattern.

Additional Clinical Pearls: All these assessments should follow the typical DSPN pattern, starting distally (the dorsal aspect of the hallux) on both sides and move proximally until a sensory threshold is identified[1,2] (Table 44.1). These sensory modalities are tested initially by application of the sensory stimulus to a body site where normal responses are expected, such as the forehead. Then the stimulus is applied to the great toe, and then moved proximally up the limb to the level where the sensation is felt to be normal. Combining at least two examinations will increase the sensitivity and specificity of detecting DSPN, as demonstrated in several cohorts of patients with T1D and T2D including children and adolescents.[1,2,7,14,20-22]

The diagnosis of DSPN is principally a clinical one (Table 44.1). A combination of typical symptomatology and symmetrical distal sensory loss, or typical signs in the absence of symptoms, in a patient with diabetes is highly suggestive of DSPN, and may not require additional evaluation or referral.[1,2] Electrophysiological testing or referral to a neurologist is rarely needed for diagnosis, except in situations where the clinical features are atypical, the diagnosis is unclear, and a different etiology is suspected.[1,23] However, the presence of atypical features that include motor deficits greater than sensory, asymmetry of symptoms and signs, and rapid progression warrants a timely referral.[1]

It is also very important to remember that several peripheral neuropathies due to causes other than diabetes may coexist in patients with diabetes, may mimic diabetic neuropathy, and may be treatable (Fig. 44.2). Thus, undertaking a thorough family and medication history and performing relevant investigations are helpful to assess other potential etiologies, such as alcohol abuse, genetic neuropathies, neoplasia, toxic exposure, and amyloidosis. Laboratory screening includes vitamin B12 levels (methylmalonic acid with or without homocysteine may provide additional information) to evaluate for B12 deficiency (particularly in patients treated with metformin), thyroid function

Metabolic disease Thyroid Renal	**Systemic disease** Vasculitis Paraproteinemia Amyloidosis	**Infectious** HIV Hepatitis B Lyme disease
Inflammatory Chronic inflammatory demyelinating polyradiculoneuropathy	**Nutritional** Vitamin B12 deficiency* Pyridoxine Thiamine Tocopherol	**Industrial agents** Acrylamide Organophosphorous agents
Drugs Alcohol Amiodarone Chemotherapy	**Heavy metals** Arsenic Mercury	**Hereditary**

*B12 deficiency is more commonly associated with malabsorption rather than nutritional deficiency

Figure 44.2 Differential diagnosis of DSPN.

tests, complete blood count, metabolic panel, and serum immunoelectrophoresis with immunofixation to evaluate for a monoclonal gammopathy and may ensure timely treatment.[1,3] Although an increasing number of genetic forms of polyneuropathy are being discovered, the role of routine genetic testing in clinical care is unclear unless patients present with distinct phenotypes suggesting genetic polyneuropathy.

Recommendations for Screening: Patients with T1D for 5 or more years and all patients with T2D should be assessed annually for DSPN using medical history and simple clinical tests.[1] As up to half of patients may be asymptomatic, a diagnosis may only be made on examination or, in some cases, when the patient presents with a painless foot ulcer.[1] Clinicians should be aware that some patients may not volunteer symptoms, but on targeted inquiry may reveal that they are experiencing numbness or other symptoms of DSPN. In addition, healthcare providers should consider screening as above patients with prediabetes/metabolic symptoms and with obesity, as well as children and adolescents.[1,3,14,24,25]

KEY POINTS

- Symptoms and signs of distal symmetric polyneuropathy (DSPN) vary depending on the class of sensory nerve fibers involved and follow a typical symmetrical, distal-to-proximal (stocking and glove) pattern.
- Neuropathic pain (burning, lancinating, tingling, or shooting electric shock–like) may be the first symptom that prompts patients to seek medical care and is due to small-fiber damage.
- Involvement of large fibers may cause numbness and tingling without pain.
- Signs of DSPN include loss of protective sensation to pain, temperature discrimination, touch, and reflexes, eventually leading to loss of balance, falls, fractures, and loss of physical function.
- Up to 50% of diabetic peripheral neuropathies may be asymptomatic.
- Early recognition and appropriate management of neuropathy in all patients with diabetes is essential to prevent serious complications.
- The diagnosis of DSPN is, in the vast majority of cases, a clinical one.
- A combination of at least two evaluations, with at least one targeting small fibers and one targeting large fibers, is recommended to screen and diagnose DSPN in routine clinical care.
- Electrophysiological testing or referral to a neurologist is not needed for diagnosis, except in situations where the clinical features are atypical, the diagnosis is unclear, and a different etiology is suspected.
- Nondiabetic neuropathies mimicking diabetic neuropathy may be present in patients with diabetes and may be treatable by specific measures; thus, a comprehensive differential is recommended.

DISTAL SYMMETRIC POLYNEUROPATHY EVALUATION IN CLINICAL RESEARCH

A valid and careful diagnosis for DSPN in clinical research is critical for correctly identifying the appropriate patient population, either for targeting for a specific intervention or for determining prognostic implications.[1,3] This is particularly relevant given that there are currently no approved disease-modifying therapies for any forms of diabetic neuropathy, and a very large number clinical trials evaluating promising experimental targets for these conditions have failed.[1] Important contributing factors include a lack of agreement and uniformity in the use of the most sensitive DSPN measures that correctly capture the natural history of the disease and may detect timely repair in the specific nerve fiber populations, as well as the inclusion of appropriate patient populations.[1]

As recommended by the Toronto Consensus on Diabetic Neuropathy,[26] for research purposes, a diagnosis of confirmed diabetic neuropathy requires a *combination of symptoms, signs, and abnormality of objective tests* such as changes in nerve conduction studies (NCSs) or, if all NCS parameters are normal, a validated measure of small nerve fibers (Table 44.2). The symptoms and signs of DSPN were broadly covered earlier in the Screening and Diagnosis in Clinical Care section. However, for research, a range of assessments including more objective measures and, importantly, patient-reported outcomes, have been developed over time and validated. The use of *validated clinical instruments* such as the MNSI (most widely used in large cohorts of patients with T1D and T2D),[3,7,10,12,14,27] the modified Toronto Clinical Neuropathy Scale,[28] the Utah Early Neuropathy Scale,[20] or the Neuropathy Disability Score[29] may be most feasible in large cohorts of patients. Table 44.3 includes the main components of and comparisons among the most sensitive and specific instruments. Among these validated clinical instruments, the MNSI has been used most consistently in largest cohorts of patients with T1D, such as DCCT/EDIC, T1D Exchange, and Scottish Registry,[5,7,9] and T2D, including the Action to Control Cardiovascular Risk in Diabetes (ACCORD), BARI 2D, GRADE, and German Diabetes Cohorts,[10,12,22,27] or in youth such as SEARCH for Diabetes in Youth Cohort (SEARCH).[14] However, for reliable results, careful training and standardizations are required.

There are multiple instruments for assessing neuropathic pain in general, with the numerical rating scale and Short-Form McGill Pain Questionnaire being widely used in most neuropathic pain trials. More recently, the DN4 (Douleur Neuropathique en 4 Questions) consisting of interview questions (DN4-interview) and a few physical tests has been validated specifically for painful DSPN, supporting its usefulness as both a screening tool for neuropathic pain and a reliable component of the diagnostic workup for painful DSPN.[30] In addition, the Quality of Life in Neurological Disorders and the Norfolk neuropathy instrument are validated instruments that capture measures of quality of life specific to peripheral neuropathy in several domains, including pain, lost/reduced feeling, diffuse sensory-motor symptoms, restrictions in activities of daily living, disruptions in social relationships, and emotional distress.[31,32]

The NCSs are performed with surface stimulating and recording techniques testing motor and sensory nerve fibers in the upper and lower limbs.[3] In diabetic neuropathy, the first changes in NCS are decrease in sural nerve amplitude, followed by mild reduction in sensory nerve conduction velocity.[3] Motor changes typically follow sensory nerve changes, and lower limb changes precede upper limb changes, as diabetic neuropathy is a length-dependent process. NCSs may be completely normal in those with primarily small fiber neuropathy, and loss of small fibers typically precedes loss of large nerve fibers.[3] The gold standard for small fiber neuropathy is assessment of intraepidermal nerve fiber density (IENFD) measurements by skin punch biopsy,[3] while other measures include quantitative sensory thermal thresholds for reduced cooling detection thresholds or elevated heat thresholds,[6] laser Doppler flare imaging studies,[33] and corneal confocal microscopy to measure nerve fiber length in Bowman's layer of the cornea, which was found to be reduced in diabetic neuropathy.[34,35] The validity of the majority of the small fiber tests, perhaps with the exception of IENFD, is not as well defined as it is for NCS, and for the moment there is no clear role for these tests in the routine clinical diagnosis of small fiber neuropathy, unless patients present with atypical phenotypes.[1,3]

KEY POINTS

- For clinical research purposes, a diagnosis of confirmed distal symmetric polyneuropathy (DSPN) requires a combination of symptoms, signs, and abnormality of objective tests, such as changes in nerve conduction studies and/or a validated measure of small nerve fibers, such as intraepidermal nerve fiber density.
- Several clinical instruments have been validated to assess DSPN in large observational or interventional cohorts.
- The Michigan Neuropathy Screening Instrument has been most widely used in large cohorts of patients with type 1 diabetes or type 2 diabetes and yields the most consistent data.
- Several instruments have also been validated to assess neuropathic pain associated with DSPN and for DSPN-associated quality of life.

Secondary Distal Symmetric Polyneuropathy Complications: Diabetic Foot Ulcers/Charcot Neuroarthropathy

DSPN is the most important cause of foot ulceration, and it is also a prerequisite in the development of Charcot neuroarthropathy, both of which are recognized as late complications of DSPN.[1] These late complications drive amputation risk and economic costs of diabetic neuropathy and are also predictors of mortality. The reader is referred to several other reviews that cover this topic.[36]

The simple yet comprehensive clinical exam is principally designed to identify those at risk of late complications who need education on preventative foot self-care and regular podiatric foot care. Recently an even simpler foot exam, the "3-minute diabetic foot exam" has been proposed.[1,36] This is intended not only for physicians, but also for other healthcare professionals who may only have 15 minutes for the entire diabetes annual review. It requires no equipment and provides simple advice on education on preventative foot self-care.

DSPN is also a major contributor to falls and fractures, through more advanced small and large fiber dysfunction, with loss of sensory, proprioception, temperature discrimination, and pain, all ultimately leading to unsteadiness, recurrent minor injuries, and an increased risk of falls.[1]

TABLE 44.2 **Distal Symmetric Polyneuropathy (DSPN) Diagnostic Criteria for Research**

Probability of DSPN	Signs, Symptoms, and Test Results
Confirmed	Sign(s) or symptom(s) of neuropathy **AND** Abnormal electrophysiology/small fiber (intraepidermal nerve fiber density)
Probable	**≥2 of the following:** Neuropathic symptoms Decreased distal sensation Decreased/absent ankle reflexes
Possible	**Any of the following:** Symptoms: decreased distal sensation, distal neuropathic sensory symptoms **OR** Signs: symmetric decreased distal sensation or decreased/absent ankle reflexes

	Michigan Neuropathy Screening Instrument (MNSI) Index	Toronto Clinical Neuropathy Score (TCNS)	Neuropathy Disability Score (NDS)
Symptoms	15 items Self-administered	6-item symptom score	None
Exam	Inspection Vibration testing Ankle reflexes	Reflex score (knee, ankle) Sensory test score (pinprick, temperature, light touch, vibration and position sense)	Sensation (vibration, temperature, pinprick) Ankle reflexes
Scoring	≥4 symptoms >2 clinical	6–8: Mild neuropathy 9–11: Moderate neuropathy ≥12: Severe neuropathy	0–2: Mild neuropathy 6–8: Moderate neuropathy 9–10: Severe neuropathy

TABLE 44.4 Number Needed to Treat and Dosing Algorithm for Most Effective Agents for Distal Symmetric Polyneuropathy Pain

Drug	Drug Class	DOSE Initial	DOSE Effective	Number Needed to Treat*
Pregabalin**	Anticonvulsant	25–75 mg one to three times daily	300–600 mg/day	3.3–7.7
Duloxetine**	Antidepressant	20–30 mg/day	60–120 mg/day	3.8–11
Gabapentin	Anticonvulsant	100–300 mg one to three times daily	1800–3600 mg/day	3.3–7.2
Amitriptyline/tricyclics	Antidepressant	10–25 mg daily	25–100 mg/day	2.1–4.2
Capsaicin 8% patch	Topical	Apply on mapped painful areas of the feet, up to a total combined surface area of 1120 cm^2 for both feet for 30 minutes		Not available

*Based on 30%–50% improvement in symptoms.

**US Food and Drug Administration–approved for distal symmetric polyneuropathy treatment.

Adapted from Pop-Busui, Boulton, Feldman et al. Diabetic neuropathy: a position statement by the American Diabetes Association. *Diabetes Care.* 2017;40:136–154.

A clinical diagnosis of small fiber neuropathy is made unless patients present with atypical phenotypes.[1,3]

KEY POINTS

- Distal symmetric polyneuropathy is the most important cause of foot ulcerations, and it is also a prerequisite in the development of Charcot neuroarthropathy.
- If not recognized, and if preventive foot care is not implemented, patients are at risk of injuries to their insensate feet.

Distal Symmetric Polyneuropathy Treatment

Disease-Modifying Therapies. Despite the recent major advances in elucidating the pathogenesis of diabetic neuropathy, there remains a lack of treatment options that effectively target the natural history of DSPN or reverse DSPN once established.[1,3] Several pathogenetic pharmacotherapies have been investigated, but evidence from randomized clinical trials is very limited.[1,3] Advances in DSPN disease modification need to be confirmed with further robust evidence from clinical trials, together with a better understanding of the mechanisms of action of promising treatment.

Prevention. Prevention of diabetic neuropathies focuses on glucose control and lifestyle modifications. Enhanced glucose control in people with T1D dramatically reduces the incidence of DSPN (78% relative risk reduction).[1,4,7] Therefore, tight glucose control targeting near-normal glycemia in patients with T1D is recommended for DSPN prevention in T1D.[1]

In contrast, enhanced glucose control in people with T2D modestly reduces the risk of developing DSPN (5%9% relative risk reduction).[1] In a small trial of Japanese patients with early T2D, intensive insulin treatment was associated with improvement in selected DSPN measures,[1] and in the ACCORD trial individuals with T2D reported a modest but significant DSPN risk reduction with the glycemia intervention after 5 years of follow-up,[27] but other trials reported no effects.[1] This discrepancy highlights the differences between T1D and T2D and emphasizes the point that many people with T2D develop DSPN despite adequate glucose control.[1] Specific glucose-lowering strategies may contribute to the discrepancy. For example, participants, particularly men, in the BARI 2D trial treated with insulin sensitizers had a lower incidence of DSPN over 4 years than those treated with insulin/sulfonylurea.[12]

There is also emerging evidence that lifestyle modifications—either exercise alone (supervised aerobics ± resistance training) or combined dietary modification and exercise—may have beneficial effects on preventing DSPN in some patients with T2D or prediabetes.[1,3]

Management of Pain in Distal Symmetric Polyneuropathy. Currently, there is no convincing evidence supporting glucose control or lifestyle management as therapies for neuropathic pain in diabetes or prediabetes.[1]

At present, pregabalin and duloxetine have received regulatory approval for the treatment of neuropathic pain associated with DSPN by the US Food and Drug Administration (FDA), Health Canada, and the European Medicines Agency.[1] Recent evidence from two large, 12-week, randomized, multicenter trials led to the FDA approval of a cutaneous concentrated capsaicin 8% patch that works by desensitizing and interfering with the function of the transient receptor potential vanilloid 1 receptor, a protein involved in pain signaling. Pain reduction was approximately 30% in these trials, but the patch needs to be applied for approximately 30 minutes. The opioid tapentadol has regulatory approval in the United States and Canada, but the evidence of its use is weak, and the ADA and other societies strongly recommend against using any opioids for management of DSPN pain.[1] The ADA Statement on Diabetic Neuropathy evaluated large datasets from published and unpublished studies to decrease the chance of publication bias and concluded that several other agents of different classes, including gabapentin and some of the monoamine reuptake inhibitors, may also be effective in reducing DSPN pain, alone or in combination, and thus recommended a stepwise approach taking into account patients' socioeconomic status, comorbidities, and potential drug interactions.[1] Table 44.4 summarizes the evidence on number needed to treat as well as dosing considerations and adverse effects for most effective agents for DSPN pain, while Fig. 44.3 shows a proposed stepwise approach. Given the high risk of addiction, abuse, sedation, and other complications and psychosocial issues even with short-term opioid use, opioids are not recommended in the treatment of painful DSPN.[1]

KEY POINTS

- There remains a lack of treatment options that effectively reverse distal symmetric polyneuropathy (DSPN), once established.
- Tight glucose control targeting near-normal glycemia in patients with type 1 diabetes (T1D) is recommended for DSPN prevention in T1D.
- Emerging evidence supports that lifestyle modifications—either exercise alone (supervised aerobics ± resistance training) or combined dietary modification and exercise—may have beneficial effects on preventing DSPN in some patients with type 2 diabetes or prediabetes.
- Several treatment options exist for pain associated with DSPN.
- Pregabalin, duloxetine, and the capsaicin 8% patch have received regulatory approval for the treatment of neuropathic pain associated with DSPN by the US Food and Drug Administration and the European Medicines Agency.
- Given the high risk of addiction, abuse, sedation, and other complications and psychosocial issues even with short-term opioid use, opioids are not recommended in the treatment of painful DSPN.

DIABETIC AUTONOMIC NEUROPATHIES

Autonomic neuropathies affect the autonomic neurons (parasympathetic, sympathetic, or both) and are associated with a variety of condition-specific symptoms and signs that should be evaluated during the medical history and physical examination of all individuals with diabetes[1]. While CAN is the most studied and clinically relevant of the diabetic autonomic neuropathies, gastrointestinal, genitourinary, and sudomotor dysfunction may also develop during diabetes course, with their direct impact in patient's quality of life and optimal management.

Cardiovascular Autonomic Neuropathy

CAN is a common and deadly complication of diabetes mellitus, which is frequently overlooked in clinical practice due to its characteristic subtle presentation earlier in disease. Yet, timely detection of CAN may help implementation of tailored interventions to prevent its progression and mitigate the risk of associated complications, including CVD, cardiac arrhythmias, myocardial dysfunction leading to congestive heart failure, and all-cause mortality.[37]

Epidemiology. There are variations in the reported prevalence of CAN depending on the population(s) studied (e.g., T1D vs. T2D, intervention trials vs. epidemiological observations, older vs. contemporary cohorts), the available outcome measures reported, and/or the diagnostic criteria used. In earlier cohorts of patients, particularly those with longstanding T1D, potential candidates for pancreas transplantation, abnormalities in cardiovascular reflex tests (CARTs) suggestive of CAN were detected in up to 90% of patients.[37] In contrast, prevalence rates are very low in patients with newly diagnosed T1D, as documented by the primary prevention arm of the DCCT cohort, arguably the best phenotyped cohort for CAN with CARTs obtained repeatedly over time.[1,4,37,38] During the observational epidemiological follow-up of the same cohort, known as the EDIC study, the prevalence of CAN increased steadily over time to as high as 44% of the cohort over 23 years of mean follow-up.[4] These data are comparable with data reported in other observational cohorts with T1D such as the EURODIAB IDDM study, which reported baseline prevalence rates of autonomic dysfunction, defined as an abnormality in one or both of the CARTs used, of 36%,[39] or the Pittsburgh Epidemiology of Diabetes Complications Study (EDC), which reported a cumulative incidence of symptomatic autonomic neuropathy over 25 years of approximately 25%.[40] Similar to T1D, prevalence rates as high as 60% have been reported in earlier cohorts of patients with longstanding T2D.[1,37] In more recent T2D cohorts, however, lower prevalence rates of 9% to 25% have been observed. For instance, in Europe, the Diabetic Cardiovascular Autonomic Neuropathy Multicenter Study Group reported CAN prevalence rates of approximately 22% in T2D using strict criteria of abnormal findings in CARTs and heart rate variability (HRV), while the observational prospective follow-up of the Danish arm of the Anglo-Danish-Dutch Study of Intensive Treatment in People With Screen-Detected Diabetes in Primary Care (ADDITION-Denmark) reported prevalence rates of 9% and 15% for manifest CAN, defined based on CARTs, at the 6-year and 13-year follow-up examinations, respectively.[41] In the United States, in more than 8000 T2D patients with a mean age of approximately 62 years and mean duration of 10 years of participants with T2D in the ACCORD trial, the prevalence of CAN at study entry was approximately 20%,[42] while the GRADE trial reported that approximately 10% of this contemporary cohort with a mean known T2D duration of 4 years presented with CAN at baseline as diagnosed with the same HRV studies.[10] In addition, CAN is present in patients with impaired glucose tolerance, insulin resistance, and/or the metabolic syndrome,[1] as well as in youth, as documented by the SEARCH for Diabetes in Youth Cohort study that included approximately 2000 youth with T1D and T2D and reported

CAN prevalence rates of approximately 12% in youth with T1D (mean age 18 years, duration of diabetes 8 years) and 17% in youth with T2D (mean age 22 years, duration of diabetes 8 years).[14]

Similarly with DSPN, notable risk factors for CAN include older age and markers of higher glycemic exposure (including longer diabetes duration and poor glucose control), diabetic kidney disease, hypertension, elevated triglycerides, and use of some medications.[1,4,37] More recently, socioeconomic factors including lower income and education, as well as depression, are emerging as risk factors for CAN.

KEY POINTS

- Cardiovascular autonomic neuropathy (CAN) is a prevalent complication in type 1 diabetes and type 2 diabetes (T2D), including in newly diagnosed T2D.
- High prevalence rates were described in individuals with prediabetes/metabolic syndrome, as well as in youth.
- Notable risk factors for CAN include older age, higher glycemic exposure, diabetic kidney disease, hypertension, elevated triglycerides, and smoking.
- Socioeconomic factors, female gender, and depression are emerging as risk factors for CAN.

Clinical Impact. A timely diagnosis of CAN has important clinical implications, as CAN is an independent risk factor for cardiovascular mortality, arrhythmia, silent ischemia, or any major cardiovascular event. Additional evidence demonstrates that CAN is an important risk factor for the development of myocardial dysfunction and heart failure in both T1D and T2D, which are emerging as underdiagnosed and important health problems in diabetes, and a predictor of the development of diabetic kidney disease.[1,37]

Screening and Diagnosis in Clinical Care. It could be quite challenging to detect CAN in its early stages in routine clinical care, as patients may be completely asymptomatic (subclinical CAN) and may only present with decreased HRV.[1,37]

Symptoms of CAN: The most common symptoms of CAN occur upon standing and include lightheadedness, weakness, palpitations, faintness, and syncope[1,37] (Table 44.5). Thus, targeted questions to unveil above symptoms should be included while a medical history is taken in the office, although the specificity of these symptoms for CAN is quite low, requiring an appropriate differential[1,37] (Table 44.5). In addition, these symptoms occur late in the disease course.[1,37] Providers may also consider screening patients at risk for developing CAN for hypoglycemia unawareness and vice versa, as this may be associated with CAN.[1,43]

Clinical Signs of Cardiovascular Autonomic Neuropathy. Physiologic HRVs re a product of both sympathetic and parasympathetic activity.[1,37] Patients with subclinical CAN present with a decrease in HRV, usually with deep breathing or change in posture, considered the earliest clinical indicator of CAN.[1,37] Although HRV testing is largely confined to the research setting, it may be done in the office by either 1) taking an electrocardiogram (ECG) recording as a patient begins to rise from a seated position or 2) taking an ECG recording during 1 to 2 minutes of deep breathing with calculation of HRV.[1] However, even these relatively simple methods could be challenging in some clinical settings, highlighting the need for easily accessible diagnostic tools and/or biomarkers for screening and diagnosis of CAN for general clinical care.

As CAN progresses, patients may present with resting tachycardia with fixed heart rate (>100 bpm; although one should be aware that resting heart rate is not specific), exercise intolerance, nondipping and reverse dipping, and in most advanced cases orthostatic hypotension (a fall in systolic or diastolic BP by >20 mm Hg or >10 mm Hg, respectively, upon standing without an appropriate increase in heart rate).[1,44] Orthostatic hypotension is usually easy to document in the office by measuring the BP supine and after standing, keeping also in mind that, in most cases of CAN, there is no compensatory increase in the heart rate, despite hypotension.[1] To document nondipping or reverse dipping, ambulatory BP monitoring, a standard tool in the current hypertension management, allows the assessment of the diurnal BP patterns that is mainly regulated by sleep-awake changes in the autonomic cardiovascular function.[1,44]

CAN diagnosis includes documentation of symptoms and signs of CAN (Table 44.5). In a symptomatic patient with a history of poor glucose control presenting with resting tachycardia or postural hypotension, clinicians may not need to perform additional CAN tests, given costs and burden, after excluding other potential causes.

As with DSPN, diagnosis of CAN requires an extensive differential, as many other comorbidities, such as CVD, adrenal insufficiency, thyroid dysfunction, acute blood loss and anemia, dehydration, and drug effects/interactions may present with symptoms and/or signs mimicking CAN, as illustrated in Table 44.5.[1,37]

Recommendations for screening in clinical care:

- All patients should be assessed for CAN starting 5 years after diagnosis or in the presence of other forms of diabetic neuropathy and/or other diabetic complications with symptoms and signs.
- Tests excluding other comorbidities or drug effects/interactions that could mimic CAN should be performed.
- Screening for CAN should also be considered in patients with hypoglycemia unawareness and high glucose variability, prior to insulin dose adjustments and/or perioperatively.[1]

KEY POINTS

- In the earliest stages, cardiovascular autonomic neuropathy (CAN) may be completely asymptomatic (subclinical CAN) and may only present with decreased heart rate variability.
- Symptoms of CAN, including palpitations, lightheadedness, weakness, palpitations, faintness, and syncope with standing, may occur only in late stages of disease.
- Signs of CAN include: resting tachycardia with fixed heart rate (>100 bpm), exercise intolerance, nondipping and reverse dipping, and orthostatic hypotension (a fall in systolic or diastolic blood pressure by >20 m mHg or >10 mm Hg, respectively).
- Cardiovascular reflex tests remain the gold standard diagnostic test.
- Diagnosis of CAN requires an extensive differential, as symptoms and signs are nonspecific (Table 44.5).
- All individuals with diabetes should be assessed for CAN starting 5 years after diagnosis or in the presence of other forms of diabetic neuropathy and/or other diabetic complications with symptoms and signs.

Cardiovascular Autonomic Neuropathy Evaluation in Clinical Research

Several tests are available to diagnose CAN, including: CARTs, ideally under paced breathing; HRV studies that derive indices in the time and frequency domains using various algorithms; 24-hour BP profiles; baroreflex sensitivity testing; and cardiac sympathetic imaging.[1,37]

CARTs remain the gold standard for autonomic testing in both clinical and research settings[1,37,44] and evaluate changes in heart rate and BP during several physiological maneuvers such as: 1) deep

TABLE 44.5 Stepwise Approach for Cardiovascular Autonomic Neuropathy Diagnosis

	Symptoms	Signs/ Diagnostic Tests	Differential Workup

Resting tachycardia	Palpitations
	Could be asymptomatic
		Clinical exam:
		Resting HR >100 bpm
			• Anemia
			• Hypothyroidism
			• Fever
			• CVD (atrial fibrillation, flutter, other)
			• Dehydration
			• Adrenal insufficiency
			• Medications
			  • Sympathomimetic agents (asthma)
			  • Over-the-counter cold agents containing ephedrine or pseudoephedrine
			  • Dietary supplements (e.g., ephedra alkaloids)
			• Smoking, alcohol, caffeine
			• Recreational drugs (cocaine, amphetamines,methamphetamine, mephedrone)

Orthostatic hypotension	Light headedness
	Weakness
	Faintness
	Visual impairment
	Syncope
		Clinical Exam:
		A reduction of >20 mm Hg in systolic BP or >10 mm Hg in diastolic BP
			• Adrenal insufficiency
			• Intravascular volume depletion
			  • Blood loss/acute anemia
			  • Dehydration
			• Pregnancy/postpartum
			• CVD
			  • Arrhythmias
			  • Heart failure
			  • Myocarditis
			  • Pericarditis
			  • Valvular heart disease
			• Alcohol
			• Medication
			  • Antiadrenergics
			  • Antianginals
			  • Antiarrhythmics
			  • Anticholinergics
			  • Diuretics
			• ACEi/ARBs
			• Narcotics
			• Neuroleptics
			• Sedatives

HR, Heart rate; *CVD*, cardiovascular disease; *BP*, blood pressure; *ACEi*, angiotensin-converting enzyme inhibitor; *ARB*, angiotensin receptor blocker.

breathing; 2) standing; and 3) a Valsalva maneuver.[1,37] Several factors may influence the results of CARTs, such as intake of caffeine, tobacco products, food, and some medications like beta-blockers. Therefore, these tests should be performed by uniformly trained personalized personnel and using standardized protocols to minimize variability and bias. In addition, given the very large number of recording devices and particularly software operating in "black-box" mode that have emerged in recent years, a careful selection of the most transparent and verifiable technologies to be used is recommended for reliable and reproducible data. In general, it is currently accepted that one abnormal test may indicate early or subclinical CAN, while two or more abnormal tests are recommended for a definite diagnosis of CAN.[44] Given that age is one of the most important factors affecting heart rate, age-related normative are needed for correct classification settings.[1,37,44]

Indices of HRV are additional CAN outcome measures that have been used extensively. The HRV can be evaluated either as time domain measures such as: the difference between the longest and shortest R–R interval, the standard deviation of 5-min average of normal R–R intervals, and the root-mean square of the difference of successive R–R intervals, or as frequency domain measures obtained by spectral analysis or other mathematical algorithms, such as: low, very low, and high frequency power.[1,37,44] Although traditionally these indices were derived from longer ECG recordings, more recently HRV-derived indices from standard 10-second 12-lead ECG recordings have emerged as more feasible alternative measures of CAN in population studies and have been shown to independently predict CVD morbidity and mortality in several large cohorts of people with and without diabetes[10,45-47] and to define prevalence rates.

Cardiac sympathetic imaging using iodine-123-labeled metaiodobenzylguanidine scintigraphy or ^{11}C-meta-hydroxyephedrine positron emission tomography, 24-hour ambulatory blood pressure monitoring profiles, baroreflex sensitivity testing to assess cardiac vagal and sympathetic baroreflex function, and microneurography, while valid and useful in some specific research scenarios, require sophisticated infrastructure and highly trained personnel and are quite expensive and time-consuming, but are widely used in research protocols.[1,37]

Several clinical instruments such as the Autonomic Symptoms Profile, the Composite Autonomic Symptom Score, and more recently the Survey of Autonomic Symptoms, which have various degrees of complexity, have also been validated to assess autonomic neuropathy in general and indirectly CAN in large cohorts.

KEY POINTS

- Cardiovascular reflex tests evaluating changes in heart rate and blood pressure during several physiological maneuvers remain the gold standard for clinical research.
- Heart rate variability–derived indices derived from standard 10-second 12-lead electrocardiogram recordings have emerged as more feasible alternative measures of cardiovascular autonomic neuropathy (CAN) in large cohorts and population studies.
- Several validated clinical instruments that offer indirect information on CAN may also be used in large cohorts.

Treatment

As it is the case with DSPN, to date no disease-modifying agents are available for CAN, likely due to the very complex pathogenic pathways contributing to CAN development.[1,37] Thus, the management of CAN includes consideration of glucose control and modification of other risk factors.

In patients with T1D, the conclusive data obtained by the DCCT, and later the EDIC study, as well as evidence from several smaller trials, strongly support that tight control of blood glucose implemented as early as possible in the disease course is very effective for preventing CAN and slowing its progression in patients with T1D.[1,4,7,37,38,48] For instance, during over an average of 6.5 years' DCCT follow-up, intensive glucose control, with lower hemoglobin A1c levels, reduced the risk of CAN by 45%, a benefit that persisted during EDIC, with a 30% reduction in incident CAN over an additional 14 years of follow-up.[4,7,38] The evidence for patients with T2D is less conclusive, as in several large cohorts intensive control of blood glucose had no effect on the risk of CAN,[49-51] although one could argue that these trials may have not included the most reliable CAN outcomes, and most enrolled patients with T2D had multiple associated comorbidities and other risk factors, such as hypertension, hyperlipidemia, and obesity, and required polypharmacy. In contrast, glucose control as part of a multifactorial intervention that also targeted hyperglycemia, hypertension, dyslipidemia, and lifestyle demonstrated a 63% reduction in the rate of progression to CAN in a small T2D cohort participating in the STENO-2 trial.[52] Most recently, analyses from the ACCORD trial reported that, after adjusting for multiple other risk factors, intensive glucose treatment significantly reduced CAN risk by 16% compared with standard intervention in a large cohort of more than 8000 T2D participants in the ACCORD trial over a mean of 5 years' follow-up.[42] These data confirmed a beneficial effect of intensive glycemic therapy, particularly in individuals without CVD at baseline. A similar benefit on CAN was found for intensive BP control,[42] while intensive treatment of hyprelipidemia with statins and fenofibrate did not. The population-based Coronary Artery Risk Development in Young Adults study reported benefit of lifestyle interventions in prevention of CAN progression.[53] In the Diabetes Prevention Program, lifestyle interventions improved measures of HRV over time in participants with prediabetes.[54]

Management of orthostatic hypotension involves both behavioral and pharmacological interventions. Behavioral supportive measures include: a) avoiding abrupt changes in body position; b) avoiding actions that elevate intraabdominal and intrathoracic pressures; c) avoiding medications that would exacerbate hypotension, such as tricyclic antidepressants, phenothiazines, and diuretics; d) raising the head of the bed during sleep; e) following a schedule of small and frequent meals to minimize postprandial hypotension; f) considering physical counter-pressure maneuvers such as leg crossing and squatting; g) hydrating with fluids and salt, if not contraindicated.[1,37] Pharmacological therapy includes midodrine and the more recent droxidopa, both of which are FDA-approved for the management of orthostatic hypotension and may be considered in patients who fail nonpharmacological interventions. However, it is recommended to proceed with a very slow titration and use the minimally effective dose to avoid undesirable side effects. In selected severe cases low-dose fludrocortisone may also be an option.[1,37]

KEY POINTS

- Similar to distal symmetric polyneuropathy, there are no available disease-modifying therapies for cardiovascular autonomic neuropathy (CAN).
- Tight glucose control is recommended to prevent CAN in type 1 diabetes.
- Glucose and other risk-factor control such as hypertension and lifestyle modifications have been shown to reduce CAN risk in type 2 diabetes.
- Management of orthostatic hypotension involves both behavioral and pharmacological interventions.
- Midodrine and droxidopa are US Food and Drug Administration–approved for the management of orthostatic hypotension, but very slow titration and using the minimally effective dose to avoid undesirable side effects are recommended.

Gastrointestinal Autonomic Neuropathy

Gastrointestinal neuropathies may involve any portion of the gastrointestinal tract, with manifestations including esophageal dysmotility, gastroparesis (delayed gastric emptying), constipation, diarrhea, and fecal incontinence.[1] Among these, gastroparesis may the most common condition providers may consider in clinical practice.

Epidemiology. Earlier prevalence data on gastroparesis are limited, given that most initial reports were from selected case series rather than larger populations, and there was inconsistency in the outcome measures use. In a large community-based study in Olmsted County, Minnesota, the cumulative incidence of gastroparesis over 10 years was higher in T1D patients (5%) compared with T2D patients (1%) and controls (1%).[55] The age–adjusted incidence of gastroparesis per 100,000 person–years was higher for women compared with men (9.8 for women and 2.4 for men), and the overall survival was found to be significantly lower than the age– and sex–specific survival of general population.[1] The prevalence of gastrointestinal symptoms that could mimic gastroparesis increased substantially in recent years in the United States and other countries, although these are nonspecific.[55,56] Additionally, the number of gastroparesis-related hospitalizations has been increasing in the United States, suggesting an increasing prevalence of gastroparesis.

KEY POINTS

- The contemporary prevalence rates of confirmed gastroparesis due to type 1 or type 2 diabetes are low.
- The prevalence of gastrointestinal symptoms that could mimic gastroparesis has increased substantially in recent years, although these are nonspecific and mainly due to iatrogenic causes.

Screening and Diagnosis in Clinical Care. Gastroparesis, one of the most common diabetic complications that providers may consider in clinical practice, can manifest with a broad spectrum of symptoms and signs.[1,57] As part of a medical history, providers are encouraged to document symptoms of gastroparesis, such as early satiety, fullness, bloating, nausea, vomiting, dyspepsia, and abdominal pain. However, all these symptoms are nonspecific and resemble many other conditions, do not correspond with severity of gastroparesis, and are poorly associated with abnormal gastric emptying.[1] Thus, gastroparesis may be clinically silent in the majority of cases and symptoms,[1] and many patients may only present with unexplained early postprandial hypoglycemia followed by later hyperglycemia.

Importantly, besides organic causes such as gastric outlet obstruction or peptic ulcer disease, hyperglycemia, hypoglycemia, and acute changes in blood glucose[58,59] are well documented to alter gastric emptying.[1] A critical consideration is that several medications widely used in patients with diabetes, especially opioids, which have been unfortunately prescribed extensively for pain management, and glucagon-like peptide-1 (GLP-1) receptor agonists, directly affect gastric emptying and could mimic gastroparesis or cause iatrogenic gastroparesis.[1]

Therefore, a thorough differential to exclude all these factors known to affect gastric emptying (including esophagogastroduodenoscopy and/or a barium study of the stomach, careful documentation of medication intake, and performing continuous glucose monitoring if available) should always be considered before considering more specialized testing is performed for gastroparesis and a firm diagnosis is established.

The diagnostic gold standard is the measurement of gastric emptying, with scintigraphy of digestible solids at 15-minute intervals for 4 hours after food intake. Optimization of glucose levels prior to scanning is needed[58,59] to avoid false-positive results. However, this test is burdensome, time-consuming, and costly, and is not readily available. Recently, the use of 13C octanoic acid breath test has been FDA-approved and emerged as a much easier to use alternative.[1]

Evaluation in Clinical Research: gastric emptying with scintigraphy of liquids and digestible solids, ideally under stable, clamped glucose levels, remains the gold standard, but is not feasible in large cohorts of participants, for which the breath tests may be more feasible. In addition, collection of full-thickness gastric tissue for detecting specific cellular changes associated with diabetic gastroparesis was developed by the National Institute of Diabetes and Digestive and Kidney Diseases Gastroparesis Clinical Research Consortium, although these studies are invasive and require specialized infrastructure, and thus may only be applicable in selected situations.

KEY POINTS

- Symptoms such as early satiety, fullness, bloating, nausea, vomiting, dyspepsia, and abdominal pain are not specific for gastroparesis.
- Gastroparesis may be clinically silent in the majority of cases, and most patients may only present with unexplained early postprandial hypoglycemia followed by later hyperglycemia.
- Several medications widely used in patients with diabetes, especially opioids, which have been unfortunately prescribed extensively for pain management, and glucagon-like peptide-1 receptor agonists, directly affect gastric emptying and could mimic gastroparesis or cause iatrogenic gastroparesis.
- Gastric emptying with scintigraphy of digestible solids remains the gold standard diagnostic test, but is burdensome, time-consuming, and costly, and is not readily available..
- Recently, the use of 13C octanoic acid breath test has been US Food and Drug Administration–approved and emerged as a much easier to use alternative.

Treatment. Treatment for diabetic gastroparesis may be very challenging and includes nonpharmacological and pharmacological options. Dietary changes, including eating multiple small meals and decreasing dietary fat and fiber intake, may be useful. In addition, improving glucose control and blunting large glucose fluctuations by optimizing the relationship between food intake and type of and pharmacokinetic profiles of glucose-lowering medications, including the use of sensor-augmented insulin pumps, will improve gastric emptying. Importantly, withdrawing drugs with effects on gastrointestinal motility, particularly opioids, but also some anticholinergics and tricyclic antidepressants, and providing appropriate education on the expected symptoms and dietary changes needed when initiating GLP-1 receptor agonists, pramlintide, and possibly dipeptidyl peptidase-4 inhibitors, will prevent unnecessary evaluations.[1] In cases of severe confirmed diabetic gastroparesis, pharmacological interventions are needed. To date, only metoclopramide, a prokinetic agent, is approved by the FDA for the treatment of gastroparesis, although with a weak level of evidence for benefits in the management of gastroparesis. Given the risk for serious adverse effects (extrapyramidal symptoms, such as acute dystonic reactions; drug-induced parkinsonism; akathisia; and tardive dyskinesia), its use in the treatment of gastroparesis beyond 5 days is no longer recommended by the FDA and the European Medicines Agency.[1] It should be reserved for severe cases that are unresponsive to other therapies.

KEY POINTS

- Dietary changes, including eating multiple small meals and decreasing dietary fat and fiber intake, may be useful.
- Improving glucose control and blunting large glucose fluctuations will improve gastric emptying.
- It is recommended to withdraw drugs with effects on gastrointestinal motility, particularly opioids, and to provide appropriate education on the expected symptoms and dietary changes needed when initiating glucagon-like peptide-1 receptor agonists, pramlintide, and possibly dipeptidyl peptidase-4 inhibitors to prevent unnecessary evaluations.
- Metoclopramide is approved by the US Food and Drug Administration (FDA) for the treatment of gastroparesis, but given the risk for serious adverse effects its use in the treatment of gastroparesis beyond 5 days, it is no longer recommended by the FDA.

Urogenital Autonomic Neuropathy

The genitourinary disturbances associated with diabetic autonomic neuropathy include sexual dysfunction in both men and women, as well as bladder dysfunction.

Epidemiology. Erectile dysfunction (ED) is three times more common in men with diabetes than those without the disease.[1,60] Sexual dysfunction is also more common in women with diabetes.[1,61] Emerging evidence also demonstrate associations between ED and other diabetes complications, including CAN and DSPN.[1,62,63] Glucose control was associated with a lower incidence of ED in men with T1D.[1] Evidence is less strong for T2D. Control of other risk factors such as hypertension and hyperlipidemia may also improve the condition.[1]

Screening in Clinical Care. Men may present ED and/or retrograde ejaculation, given that autonomic neurotransmission controls the cavernosal and detrusor smooth muscle tone and function.[1] The etiology, however, is multifactorial, and clinicians should also evaluate other vascular risk factors such as hypertension, hyperlipidemia, obesity, endothelial dysfunction, smoking, CVD, concomitant medication, and psychogenic factors.[1] A diagnosis should be made after establishing the signs and symptoms of ED and after excluding alternate causes. Clinicians should consider performing hormonal evaluation (luteinizing hormone, testosterone, free testosterone, prolactin) to rule out hypogonadism. In addition, a variety of medications (such as beta-blockers) and organic causes should be excluded.[1]

It is recommended that clinicians screen men with other forms of diabetic neuropathy annually for ED with simple questions about a patient's libido and ability to reach and maintain an erection.[1]

Female sexual dysfunction (FSD) presents as decreased sexual desire, increased pain during intercourse, decreased sexual arousal, and inadequate lubrication.

Bladder dysfunction may manifest as nocturia, frequent urination, urination urgency, and weak urinary stream, and may also coexist with lower urinary tract symptoms (LUTS) such as urinary incontinence, and recurrent urinary tract infections.[1] Thus, it is also recommended that clinicians screen patients with other forms of diabetic neuropathy for FSD and LUTS. Evaluation of bladder function should be performed for individuals with diabetes who have recurrent urinary tract infections, pyelonephritis, urinary incontinence, nocturia, or a palpable bladder. In addition, FSD could be documented using targeted questioning regarding symptoms, such as nocturia or pain during intercourse.[1]

Treatment. Pharmacological treatment for ED includes phosphodiesterase type 5 inhibitors as first-line therapy, and in more advanced cases, transurethral prostaglandins, intracorneal injections, vacuum devices, and penile prosthesis.[1] FSD treatment is much more complex and challenging.

KEY POINTS

- Erectile dysfunction (ED), female sexual dysfunction (FSD), and bladder dysfunction are common in men and women with diabetes and have direct links with autonomic neuropathy.
- Clinicians should consider screening men who present with other forms of diabetic neuropathy annually for ED with simple questions about a patient's libido and ability to reach and maintain an erection.
- Bladder dysfunction may manifest as nocturia, frequent urination, urination urgency, and weak urinary stream.
- FSD could be documented using targeted questioning regarding symptoms, such as nocturia or pain during intercourse.
- Phosphodiesterase type 5 inhibitors remain the first-line therapy for ED.
- FSD treatment is much more complex and challenging.

Sudomotor Dysfunction

Sudomotor dysfunction may manifest as dry skin, anhidrosis, heat intolerance, or in rare cases gustatory sweating.[1] The latter is a very rare form of sudomotor dysfunction comprising excessive sweating limited exclusively to the head and neck region usually triggered by food consumption, and is described in patients with more advanced autonomic neuropathy and/or on dialysis.[64]

Based on the available evidence, routine screening for sudomotor dysfunction in clinical practice is not recommended at this time.[1]

ATYPICAL NEUROPATHIES

Mononeuropathies

Mononeuropathies occur as a result of involvement of the median, ulnar, radial, and common peroneal nerves and are more common in patients with diabetes.[1] Cranial neuropathies are very rare, primarily involve cranial nerves III, IV, VI, and VII, and usually resolve spontaneously over several months.[1] Electrophysiological studies are most helpful in identifying nerve conduction slowing or conduction block at the site of nerve entrapment. Nerve entrapments may require surgical decompression. The improvement in symptom severity and functional status score is no different between patients with and without diabetes.[1]

Diabetic Radiculoplexus Neuropathy

Diabetic radiculoplexus neuropathy (diabetic amyotrophy or diabetic polyradiculoneuropathy) typically involves the lumbosacral plexus.[1] People with the condition routinely present with extreme unilateral thigh pain and weight loss, followed by motor weakness. Electrophysiological assessment is required to document the extent of disease and alternative etiologies, including degenerative disc disease, neoplastic, infectious, and inflammatory spinal disease.[1] The disorder is usually self-limiting, patients improve over time with medical management and physical therapy, and there is presently no evidence from randomized trials to support any recommendation on the use of any immunotherapy treatment in this condition.[1]

CONCLUSIONS

Diabetic neuropathies are prevalent and have a diverse clinical spectrum of symptoms and signs. By far the most common forms are DSPN and CAN, and pain may be an initial symptom that triggers medical attention. Given its high morbidity and mortality risk, an earlier diagnosis is recommended. In most cases, accurate recording of symptoms, as described by the patient, a careful clinical examination, use of simple instruments (e.g., the MNSI), and foot inspection are sufficient for daily clinical practice. More sophisticated diagnostic tests or procedures, including referral to neurologists or electrophysiology, are rarely needed and are reserved for atypical and rapidly progressing cases. Treatment of diabetic neuropathies is challenging, often requiring a team approach. Glucose control (especially for patients with T1D), effective treatment of pain, and measures to prevent foot ulcerations remain the mainstay of treatment.

Summary and Future Directions, 785

Diabetic kidney disease (DKD) is one of the most consequential complications of diabetes. DKD is defined as a sustained elevation of urinary albumin excretion (urine albumin-to-creatinine ratio [UACR] >30 mg/g) or a reduction in estimated glomerular filtration rate (eGFR) to less than 60 ml/min/1.73 m^2.[1] DKD develops in approximately one-third of patients with type 1 diabetes mellitus (T1DM) and half of patients with type 2 diabetes mellitus (T2DM).[1-3] The epidemiology of this microvascular complication has substantially changed over time. Whereas in the early 1970s DKD was classified as a relatively rare cause of kidney disease, constituting only 3% of patients transitioning to kidney replacement therapy (KRT), several decades later DKD has become both the leading cause of kidney failure classified as end-stage kidney disease (ESKD) and the most frequent indication for KRT.[4-6] Closely mirroring the diabetes pandemic, DKD has become a major public health problem worldwide.[7] In contrast to the morbidity and mortality associated with other diabetic complications (myocardial infarction, stroke, limb amputation) that are trending downward, the number of cases of DKD progressing to kidney failure or ESKD and kidney-related deaths continues to climb.[8-10] Besides the impending risk for progression to kidney failure, patients with DKD are at notably higher risk of experiencing cardiovascular events, stroke, infections, hospitalizations, and death.[11-14] A disproportionate burden of the increase in DKD (63%) has occurred in lower-middle income countries.[15] In these regions, KRT is only accessible to 9% to 16% of patients with kidney failure.[16-17] Soberingly, it is estimated that in the year 2010 alone more than 2.2 million individuals with kidney failure worldwide died owing to lack of KRT access.[18] Rates of kidney failure, largely driven by diabetes, continue to increase and are projected to double by the year 2030.[7,16]

Given the enormous humanistic and societal impact of DKD, improved approaches to prevention and treatment are critical to improving outcomes. This chapter outlines the complex pathophysiology and natural history of DKD. It offers an overview of best practices for DKD diagnosis, classification, and comprehensive care. Treatment of DKD is discussed with emphasis on the established standard of care, along with the newer classes of glucose-lowering agents within the sodium-glucose cotransporter 2 (SGLT-2) inhibitor and glucagon-like peptide-1 (GLP-1) receptor agonist classes.

EPIDEMIOLOGY

The reported prevalence of DKD varies depending on the methodology and the geographic setting. In the United States, studies have reported the prevalence of DKD to range between 26% and 44%.[19] These data align with occurrence of DKD in approximately one-third of patients with T1DM and up to half of patients with T2DM. The increase in prevalence of DKD parallels the increased prevalence of diabetes in the same time periods.[19] Progressively increasing trends continued between 2002 and 2016, with the total burden of chronic kidney disease (CKD) increasing by 53%, which was primarily driven by DKD. Moreover, 90% of all new cases of diabetes-attributable kidney failure occur in T2DM.[6,20] From 1990 to 2016, the global incidence and prevalence of CKD increased by 89% and 87%, respectively, and the death rate because of CKD increased by 98%.[15] Similar to trends reported in the United States, this upsurge is attributed to growth in the global age-standardized prevalence of DKD.[15] The United Kingdom Prospective Diabetes Study (UKPDS), which enrolled newly diagnosed T2DM participants, offered an opportunity to determine incident DKD. After median follow-up of 15 years, 38% developed albuminuria, 29% developed creatinine clearance less than 60 mL/min or doubling of plasma creatinine, and 14% developed both conditions.[3] A metaanalysis of 71 studies reported the annual incidence of albuminuria at 8% in T2DM and 2% to 3% in T1DM, while the incidence of developing eGFR less than 60 mL/min/1.73 m^2 was 2% to 4% per year, regardless of diabetes type[21] (Box 45.1).

BOX 45.1 EPIDEMIOLOGY OF DIABETIC KIDNEY DISEASE

- The number of people with diabetic kidney disease (DKD) is increasing globally in parallel to the diabetes pandemic.
- The worldwide incidence and prevalence of DKD increased by 90% from 1990 to 2016.
- DKD is the leading cause of kidney failure and need for kidney replacement therapy.

KEY POINTS

- In parallel to the diabetes pandemic, the incidence and prevalence of diabetic kidney disease in the 1990–2016 time span increased by 90%. This establishes diabetic kidney disease as a worldwide leading cause of kidney failure and kidney replacement therapy.

RISK FACTORS

Risk factors for DKD can be classified as those promoting susceptibility, initiation, and progression. These risk factors may influence more than one process (Table 45.1).[22] Demographic risk factors such as age, sex, and race/ethnicity are nonmodifiable. Both the incidence and the prevalence of DKD increase with age. Indeed, older age is an important predictor of progressive albuminuria and eGFR decline in diabetes.[23,24] Male sex is a risk factor for eGFR decline in T2DM, although women have a higher prevalence of diabetes.[25-27] In women, DKD typically develops more than 10 years later than in men, such that postmenopausal women have higher risk for developing DKD and progressing to kidney failure.[28-30] Global reports indicate that some racial or ethnic groups have greater susceptibility and worse prognosis for DKD.[31] People of South Asian, African American, Native American, Pacific Islander ancestry, or Hispanic ethnicity have a higher risk of eGFR decline, compared with people of European descent.[32-40] However, determining an independent association of race or ethnicity with DKD is complicated by potential differences in socioeconomic status or access to care that may influence these relationships.[35]

In terms of hereditary risk factors, early studies found an increased risk of DKD in family groupings, suggesting inherited susceptibility. The diabetic offspring of parents with DKD have a cumulative DKD risk of greater than 70%, with a 3- to 4-fold higher incidence compared with children of diabetic parents without DKD.[41-43] Although genome-wide association studies for genetic predisposition to DKD have thus far not produced conclusive results, epigenetic changes as a predisposition to DKD are being increasingly recognized.[44,45] Epigenetic predisposition has been demonstrated in multiple studies. For instance, in patients with T1DM, levels of DNA methylation correlate with time to DKD development.[46] A study that compared DNA methylation levels in Black American and Latino patients with kidney failure owing to DKD to those without DKD found that approximately 20% of the genes exhibiting different methylation between the two groups had been previously implicated in CKD or DKD in other genome-wide association or transcription profiling studies.[47] A majority (24 out of 30) of the top DNA methylation markers associated with GFR changes were related to aging, inflammation, or lipid pathways.[48]

Exposure to maternal diabetes during gestation is associated with higher risk of DKD and high birth weight (≥4500 g).[31] When compared with individuals not exposed to gestational hyperglycemia, the offspring of mothers with T1DM demonstrate alterations in the DNA methylation profile and kidney hemodynamics (GFR and blood flow) indicating reduced kidney reserve that implies susceptibility to DKD.[49,50] Notably, both low (<2500 g) and high (≥4500 g) birth weight have been associated with higher risk of albuminuria in the offspring of diabetic mothers.[51-54] For low birth weight infants, the proposed mechanism underlying higher risk of DKD is growth retardation with low nephron number that predisposes to development of kidney disease and hypertension.[51-54] In contrast, the Finnish Diabetic Nephropathy study did not find a relationship between low birth weight and DKD.[55]

The presence of obesity often precedes the diagnosis of T2DM by years or decades and may exert an additive effect on risk of DKD.[56] One study of obese participants with T2DM and preserved kidney function demonstrated a significantly faster age-adjusted annual eGFR decline (–1.2 ± 0.1 mL/min/1.73 m^2 per year) compared with normal weight individuals.[57] The mechanism(s) by which obesity increases DKD risk is not clearly elucidated, but may include inflammation, abnormal fatty acid metabolism, hemodynamic abnormalities, and exacerbation of hypertension and insulin resistance.[58-61]

Key modifiable risk factors for development and progression of DKD are hyperglycemia and hypertension. The association of glycemic control and microvascular complications has been well described in both T1DM and T2DM. Evidence supporting intensive glycemic control early in the course of diabetes comes from two landmark trials: the Diabetes Control and Complications Trial (DCCT), with follow-up within the Epidemiology of Diabetes Interventions and Complications (EDIC) study in T1DM and the UKPDS in T2DM.[62-64] During the 20-year follow-up period of the ongoing EDIC study, the glycated hemoglobin (HbA1c) difference (7.3% vs. 9.1% during active study in the intervention and control groups, respectively) dissipated, such that the subsequent mean HbA1c was approximately 8% in both groups.[62,63] Despite equalization of overall glycemic control, an analysis including 9 years of EDIC data showed that the intensive glycemic control group exhibited 34% and 56% lower risks of developing microalbuminuria and macroalbuminuria, respectively.[65] After 22 years of follow-up, intensive glycemic control was associated with 50% lower risk of developing eGFR less than 60 mL/min/1.73 m^2 and kidney failure, as well as a slower rate of eGFR loss (–1.56 mL/min/1.73 m^2 per year in the standard therapy group versus –1.27 mL/min/1.73 m^2 per year in the intensive therapy group).[66] Between-group differences in glycemic control of newly diagnosed T2DM patients were lost 1 year into the posttrial follow-up stage of the UKPDS study.[67] Nevertheless, 10 to 12 years of posttrial follow-up showed a 24% reduction in risk of microvascular complications, including macroalbuminuria, as well as a reduction in the rate of serum creatinine doubling in the intensive compared with the conventional therapy group (0.9% vs. 3.5%, $P = .0028$).[68,69] This “metabolic memory” in response to early intensive glycemic control highlights its importance from diabetes onset to prevent DKD. Epigenetic alterations may be an important contributor to metabolic memory in DKD.[45] In a study of DCCT/EDIC participants who developed DKD, a set of abnormal DNA methylation patterns persisted for 17 years during follow-up into the EDIC study, irrespective of glycemic control.[70]

Blood pressure control is another central component of DKD prevention and treatment. An analysis of UKPDS participants followed for a median of 15 years showed that a target blood pressure of less than 150/85 mm Hg when compared with a target blood pressure of less than 180/105 mm Hg resulted in a 39% reduced risk for microvascular complications.[71] Overall, each 10 mm Hg increase in mean systolic blood pressure (SBP) was associated with a 13% increase in the hazard ratio for development of both microalbuminuria and macroalbuminuria and eGFR less than 60 mL/min/1.73 m^2 or a doubling of the serum creatinine.[71] A *post hoc* analysis of the Reduction of Endpoints in Non–Insulin-Dependent Diabetes Mellitus with the Angiotensin II

TABLE 45.1 Risk Factors for Diabetic Kidney Disease

Risk Factor	Susceptibility	Initiation	Progression

Antagonist Losartan study demonstrated that SBP was an independent risk factor for kidney failure. A baseline SBP in the range of 140 to 159 mm Hg increased risk for ESKD or death by 38% compared with a SBP less than 130 mm Hg.[72] An analysis of the Irbesartan Diabetic Nephropathy Trial data showed that a baseline SBP greater than 149 mm Hg associated with 2.2-fold higher risk for doubling of serum creatinine or kidney failure compared with SBP less than 134 mm Hg.[73] Progressive lowering of SBP to 120 mm Hg was associated with reduced risk for doubling of serum creatinine or kidney failure, as well as for survival, independent of baseline kidney function.[73]

Diabetes is a risk factor for acute kidney injury (AKI). Patients with diabetes undergoing surgical procedures or suffering from acute illness have a high risk of AKI. Notably, children with T1DM hospitalized with diabetic ketoacidosis (DKA) also have increased risk of AKI.[74] However, AKI may also occur in the absence of an obvious precipitating event.[75-77] Single or multiple repetitive episodes of AKI significantly increase the risk of developing DKD and progression to kidney failure.[78,79]

High blood amino acids levels induce glomerular hyperfiltration, a major mechanism of hemodynamic injury to the diabetic kidney. As such, excess dietary protein intake can promote initiation and progression of DKD. High dietary protein intake is associated with development of albuminuria, decline in eGFR, and cardiovascular mortality.[80-82] In contrast, lower dietary protein intake reduces glomerular hyperfiltration and may slow progression of DKD.[83,84] In patients with T1DM, a diet with lower (0.89 g/kg/day) compared with higher (>1g/kg/day) protein intake resulted in a reduced rate of kidney failure (10% vs. 27%, $P = .042$).[85] A metaanalysis of eight studies showed that the benefit of a low-protein diet was mainly on albuminuria reduction in diabetic patients.[86] Notably, these studies were underpowered to assess effects on clinical outcomes. As albuminuria is highly associated with future risk of eGFR decline, a lower protein diet or avoidance of excessive protein intake are considered favorable for DKD overall (Box 45.2).

BOX 45.2 RISK FACTORS FOR DIABETIC KIDNEY DISEASE

- Nonmodifiable risk factors associated with diabetic kidney disease (DKD) include age, sex, and ethnicity.
- A family history of DKD increases DKD risk.
- Hyperglycemia and hypertension control are key modifiable risk factors for development and progression of DKD.
- Hyperglycemia early in the course of disease leads to "metabolic memory" that impacts future risk of DKD.

KEY POINTS

- Uncontrolled hyperglycemia early in the course of diabetes leads to "metabolic memory" and together with hypertension control are the most important modifiable risk factors for development and progression of diabetic kidney disease.

DIAGNOSIS AND CLASSIFICATION

DKD refers to a diagnosis of CKD in a patient with diabetes without another known or likely cause. CKD is established by two abnormal measurements of laboratory markers that indicate kidney damage or

TABLE 45.2 Categories of Chronic Kidney Disease by Estimated Glomerular Filtration Rate and Albuminuria

Stage	Description	Estimated Glomerular Filtration Rate (mL/min/1.73 m^2)
G1	Normal or high	≥90
G2	Mildly decreased	60–89
G3a	Mildly to moderately decreased	45–59
G3b	Moderately to severely decreased	30–44
G4	Severely decreased	15–29
G5	Kidney failure	<15

Stage	Description	Albuminuria	
A1	Normal to mildly increased	<30 mg/g	<3 mg/mmol
A2	Moderately increased	30–300 mg/g	3–30 mg/mmol
A3	Severely increased	>300 mg/g	>30 mg/mmol

(Modified from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl.* 2013;3:1–150.)

loss of function, at least 3 months apart. These CKD markers are albuminuria, low eGFR, or both. Moreover, the presence of retinopathy, diabetes duration longer than 5 years in T1DM, or diabetes duration longer than 10 years in T2DM are highly predictive of classical diabetic glomerulopathy.[1,87,88] The preferred test for albuminuria is UACR performed on a random urine spot sample, if possible in the morning. Increased urinary albumin excretion is defined as a UACR of 30 mg/g or more. The eGFR is calculated from the serum creatinine concentration using either the Modification of Diet in Renal Disease or Chronic Kidney Disease-Epidemiologic Prognosis Initiative (CKD-EPI) equations. The CKD-EPI equation is now preferred because it has greater precision at higher levels of eGFR (>60 mL/min/1.73 m^2).[89] The serum cystatin C level can also be used to calculate eGFR by the CKD-EPI equation, either alone or combined with the serum creatinine level, which provides even greater precision for eGFR.[90] However, cystatin C is not standardized or available in many laboratories.

Kidney biopsy is not routinely performed to diagnose DKD. However, a diagnostic kidney biopsy may be considered if there is a clinical suspicion for an alternative diagnosis, or if there are atypical features of DKD such as rapid eGFR decline, abrupt increase in albuminuria, a nephritic syndrome, or signs or symptoms of another systemic disease.[1,87] Annual measurements of albuminuria and serum creatinine are recommended for people with T1DM beginning 5 years after the diagnosis, and for all T2DM patients beginning the time of diagnosis of diabetes (Table 45.2).[1,88,91,92] If there is a change in clinical status (progression to a more advanced CKD stage) or medication (renin angiotensin system inhibitor or an SGLT-2 inhibitor), then UACR and eGFR should be measured more frequently (every 3–6 months). Referral to a nephrologist is recommended if there is need for further diagnostic evaluation or management guidance, or if the eGFR is less than 30 mL/min/1.73 m^2 (Box 45.3).[1,87]

Biomarkers

Use of serum creatinine to measure eGFR has limitations, such as variability depending upon age, sex, and muscle mass. Addition of serum cystatin C to the CKD-EPI equation is recommend to increase precision for eGFR over 60 mL/min/1.73 m^2.[90] Limitations related to measurements of albuminuria include lack of specificity and sensitivity, with up to 40% day-to-day variability.[88,93-96]

BOX 45.3 DIAGNOSIS OF DIABETIC KIDNEY DISEASE

- Diabetic kidney disease (DKD) is diagnosed by microalbuminuria (urine albumin-to-creatinine ratio [UACR] 30–300 mg/g), macroalbuminuria (UACR >300 mg/g), estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2, or a combination of high albuminuria and low eGFR that persists for at least 3 months in a person with diabetes.
- Annual screening for DKD is recommended within 5 years of a diagnosis of type 1 diabetes mellitus and beginning at the time of diagnosis of type 2 diabetes mellitus.
- If there is a change in clinical status (progression to a more advanced chronic kidney disease category) or medications that can impact UACR and/or eGFR (renin angiotensin system inhibitor or sodium-glucose cotransporter 2 inhibitor), then UACR and eGFR should be measured more frequently (every 3–6 months).
- Referral to a nephrologist is recommended if there is need for further diagnostic evaluation or management guidance, or if the eGFR is <30 mL/min/1.73 m^2.

New biomarkers that will advance DKD diagnosis, risk stratification, monitoring, and prognosis are an active area of investigation. Several studies assessed individual or panels of biomarkers representing different pathways or processes involved in the pathogenesis of DKD using urinary proteomics or metabolomics.[97-99] Promising candidates include soluble tumor necrosis factor receptors (TNFR1 and TNFR2) and kidney injury molecule-1 (KIM-1).[100] These biomarkers were found to be 2-fold higher among those with advanced DKD compared with earlier stages of disease and predicted eGFR decline and kidney failure.[101] Similarly, urinary monocyte chemoattractant protein-1 (MCP1) levels were elevated in diabetic patients with macroalbuminuria and were prognostic for deterioration in eGFR.[102] Analysis of Chronic Renal Insufficiency Cohort Study participants with DKD and eGFR less than 60 mL/min/1.73 m^2 at baseline demonstrated that, in addition to TNFR1, TNFR2, and MCP1, higher plasma levels of soluble urokinase-type plasminogen activator receptor and YKL-40 were associated with increased risk of progression of DKD.[103] Epigenetic studies have identified signatures of specific DNA methylation sites, histone posttranslational modifications, and urinary microRNAs (miRNAs) that are associated with low eGFR or albuminuria.[45,104] However, no new candidates have meaningfully outperformed traditional DKD biomarkers for risk prediction. Albuminuria remains the best predictor of DKD progression and kidney failure.[105]

KEY POINTS

- Annual screening for diabetic kidney disease should start within 5 years of a diagnosis of type 1 diabetes mellitus or at the time of diagnosis of type 2 diabetes mellitus, and is established by presence of microalbuminuria (urine albumin-to-creatinine ratio [UACR] 30–300 mg/g), macroalbuminuria (UACR >300 mg/g), estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2, or a combination of high albuminuria and low eGFR that persists for at least 3 months.

NATURAL HISTORY

The traditional model for the natural history of DKD centers around development of glomerular hyperfiltration that progresses to increasing albuminuria followed by declining eGFR (Fig. 45.1).[106] However, it is clear that DKD can present with low eGFR and without albuminuria.[107]

Timeline is well characterized for type 1 diabetes mellitus; for type 2 diabetes mellitus, timeline may depart from the illustration because of the variable timing of the onset of hyperglycemia. *Kidney complications: anemia, bone and mineral metabolism, retinopathy, and neuropathy. *GFR,* Glomerular filtration rate. (From Alicic RZ, Rooney MT, Tuttle KR. Diabetic kidney disease: challenges, progress, and possibilities. *Clin J Am Soc Nephrol.* 2017; 12:2032–2045.)

For instance, over a median follow-up of 15 years of patients with newly diagnosed T2DM in the UKDPS, 40% developed albuminuria, and 30% progressed to an eGFR under 60 mL/min/1.73 m^2 or experienced a doubling in serum creatinine. Of participants experiencing a decline in kidney function, 60% did not have preceding albuminuria.[3] Further support for this observation came from the Developing Education on Microalbuminuria for Awareness of Renal and Cardiovascular Risk in Diabetes study, with approximately 21%, 31%, and 35% of individuals with normoalbuminuria, microalbuminuria, and macroalbuminuria, respectively, developing a creatinine clearance of less than 60 mL/min/1.73 m^2.[93] The clinical presentation of DKD has shifted such that the prevalence of low eGFR in the absence of albuminuria occurs more commonly. Indeed, a study comparing DKD presentation during the time periods of 1988 to 1994 and 2009 to 2014 reported that the prevalence of albuminuria decreased from 21% to 16%, while the prevalence of low eGFR (<60 mL/min/1.73 m^2) and severely reduced eGFR (<30 mL/min/1.73 m^2) increased from 9% to 14%, and 1% to 3%, respectively.[92] The classical paradigm of DKD is further challenged by findings that albuminuria may be dynamic and fluctuating rather than linearly progressive. For example, during nearly 8 years of follow-up in the Multifactorial Intervention for Patients with Type 2 Diabetes Study, 31% of participants with microalbuminuria progressed to macroalbuminuria, 38% remained microalbuminuric, and 31% regressed to normoalbuminuria.[108] Another study demonstrated remission of microalbuminuria to normoalbuminuria in 24% of cases and regression of macroalbuminuria to microalbuminuria in 30% of cases.[109]

Only limited data on the natural history of DKD by diabetes type are available. In general, albuminuria rates appear to be similar in patients with T1DM and T2DM. However, low eGFR is more common in T2DM.[110] In terms of progression to kidney failure, rates of eGFR decline can be highly variable between patients. Data are also mixed regarding whether the incidence of kidney failure differs by type of diabetes.[111-112] Data from patients with T1DM and T2DM registered in Australia's National Diabetes Services Scheme showed that the age-standardized annual incidence of kidney failure increased for people with T2DM and remained stable for patients with T1DM from 2002 to 2013 (Box 45.4).[112]

BOX 45.4 NATURAL HISTORY OF DIABETIC KIDNEY DISEASE

- Estimated glomerular filtration rate (eGFR) decline is faster in association with albuminuria, especially macroalbuminuria, but may also occur in non-albuminuric patients.
- The natural history of diabetic kidney disease (DKD) appears to be similar in both types of diabetes.
- Patients with DKD are more likely to have anemia compared with patients with nondiabetic chronic kidney disease at comparably reduced levels of eGFR.
- Insulin resistance in patients with diabetes contributes to lower parathyroid hormone levels with an increased predisposition to adynamic bone disease.

DKD produces hormonal changes that often contribute to complications of kidney failure earlier than in nondiabetic CKD. Because of a prominent tubulointerstitial component of DKD, damage to erythropoietin-producing peritubular interstitial cells occurs with consequent erythropoietin deficiency. Therefore, patients with DKD are nearly twice as likely to have anemia compared with patients with nondiabetic CKD at comparably reduced levels of eGFR.[22] Insulin resistance in patients with diabetes contributes to lower parathyroid hormone levels, with an increased predisposition to adynamic bone disease.[113]

KEY POINTS

- The natural history of diabetic kidney disease is similar in both types of diabetes. Estimated glomerular filtration rate declines faster in association with albuminuria, especially macroalbuminuria, but may also occur in nonalbuminuric patients. Patients with diabetic kidney disease are more likely to have anemia compared with patients with nondiabetic chronic kidney disease at comparably reduced levels of kidney function, and lower parathyroid hormone levels with an increased predisposition to adynamic bone disease.

STRUCTURAL CHANGES OF THE KIDNEY

Structural changes of DKD occur within multiple kidney compartments.[114] The earliest changes are enlargement of the kidney because of glomerular and tubular hypertrophy.[115,116] Additionally, glomerular basement membrane (GBM) thickening is evident as early as 1.5 to 2 years following a diagnosis of T1DM.[117-119] Glomerular and tubular hypertrophy may be driven by activation of growth factors within the diabetic milieu,[120] whereas increased formation of glycated proteins and mechanical stress of glomerular hyperfiltration are implicated in the thickening of GBM (Fig. 45.2). Other features of early DKD include expansion of the glomerular mesangium.[121-122] In part because of an adaptive response to the thickening GBM, podocytes hypertrophy, flatten, and detach. Eventually severe loss of podocytes ensues, leaving large subepithelial surfaces of the GBM denuded.[122-124] Progression of the structural glomerular changes include thickening of Bowman's capsule and greater glomerular mesangial expansion owing to increased mesangial matrix and, to a lesser extent, increases in mesangial cellularity.[125] The mesangial matrix expansion often develops into a form of nodular glomerulosclerosis known as Kimmelstiel-Wilson nodules. Plasma proteins, or hyaline material, often accumulate between the glomerular endothelium and the GBM and between the glomerular tuft and Bowman's capsule (Fig. 45.3).[126-128] The tubulointerstitium progressively develops fibrosis and inflammation, thickening of the tubular basement membranes, and tubular atrophy.[129] The blood vessels display arteriosclerosis and hyalinosis, particularly at the vascular pole. The tubulointerstitial damage progresses in concert with glomerulosclerosis. In advanced stages, global glomerular sclerosis with severe interstitial fibrosis and tubular atrophy are evident (Fig. 45.4).[128] The international Renal Pathology Society work group developed a histopathological classification system to describe and grade the severity of DKD.[130]

Structural changes in DKD are similar in the setting of T1DM and T2DM, but the pathological findings and correlations with the clinical presentation are less predictable in T2DM.[131] For instance, an autopsy study of predominantly T2DM (90%) patients found that twenty out of 106 histologically proven cases of DKD did not have a clinical diagnosis of DKD while alive, and specifically did not have albuminuria.[96] Structural changes in this cohort encompassed the spectrum of histopathological classes of DKD.[96] These findings were confirmed in diabetic kidney transplant donors (98% T2DM) in whom structural changes preceded clinical evidence of DKD (Box 45.5).[132]

KEY POINTS

- Structural changes involve all kidney compartments and are similar in patients with type 1 diabetes mellitus and type 2 diabetes mellitus. The earliest changes are glomerular and tubular hypertrophy, followed by glomerular basement thickening, podocyte foot process effacement and detachment, mesangial expansion and formation of Kimmelstiel–Wilson nodules, glomerulosclerosis, tubulointerstitial fibrosis and inflammation, and arteriolar hyalinosis and arteriosclerosis.

PATHOPHYSIOLOGY

The metabolic, hemodynamic, inflammatory, fibrotic, and epigenetic changes induced by the diabetic milieu trigger a complex, multidirectional, self-perpetuated cascade leading to structural and functional abnormalities associated with DKD (Fig. 45.5, Box 45.6).

Increased Glucose Uptake in the Diabetic Kidney

Important contributions of the kidney to glucose homeostasis are reabsorption of glucose from the glomerular filtrate and gluconeogenesis.[133] Glucose reabsorption takes place in the cells of the proximal tubule via apically located SGLT-1 and SGLT-2, and through facilitative glucose transporters (GLUTs) located on the basolateral side of

the tubular cells.[134-136] The majority of the reabsorption takes place in the early segment of the proximal tubule via coupling of SGLT-2 and GLUT-2 transporters. Only approximately 10% of glucose is reabsorbed via SGLT-1 and GLUT-1 in the S3 segment of the proximal tubule.[137] A landmark trial published in 1971 demonstrated increased uptake of glucose in the proximal tubule in diabetic patients, thus indicating enhanced reabsorption transport capacity in diabetes.[138] Indeed, the threshold for glucosuria in diabetes is in the range of 200 to 240 mg/dL, which is increased from the threshold of 100 to 240 mg/dL reported under physiological conditions.[135] The increase in resorptive capacity in diabetes is a result of increased SGLT and GLUT transporters driven by increased mRNA expression and production. Support for this hypothesis comes from experimental models of diabetes. Mouse and rat models, as well as studies using tubular epithelial cells isolated from the urine of diabetic patients, report increased expression of SGLT-1, SGLT-2, GLUT-1, and GLUT-2 proteins.[139-145] Increased glucose and sodium chloride uptake in the proximal tubule via SGLT-2 reduces solute delivery to the macula densa and significantly contributes to a vasoactive imbalance between the preglomerular (afferent) and postglomerular (efferent) arterioles, resulting in glomerular hyperfiltration (Fig. 45.6).[22,146]

Hemodynamic Abnormalities

Glomerular hyperfiltration is driven by an increase in the glomerular capillary pressure.[116,147] Glomerular hyperfiltration is present in about 75% of patients with T1DM and in approximately 40% of patients with early T2DM.[148-150] Even though increased glomerular plasma flow, hyperfiltration, and hypertension are typically associated with diabetes, these hemodynamic aberrations are also found in patients with prediabetes and obesity.[151-152] Although the exact mechanism is unclear, hyperglycemia, abnormal insulin levels, and dietary proteins are all important mediators.[115,153-155] Major factors contributing to increased efferent arteriolar resistance (vasoconstriction) include activation of the renin-angiotensin system, with increased production of angiotensin II and endothelin-1, whereas reduction of afferent arteriolar resistance (vasodilation) is driven by inhibition of tubuloglomerular feedback. Tubuloglomerular feedback is an autoregulatory mechanism that adjusts GFR in response to the concentration of sodium chloride delivered to the macula densa segment of the distal convoluted tubule. A byproduct of sodium reabsorption is adenosine produced by utilization of adenosine triphosphate for active sodium–potassium exchange on the basolateral side of macula densa cells. Adenosine release produces a paracrine effect to increase afferent arteriolar resistance (vasoconstriction). In diabetes, increased sodium and glucose reabsorption in the proximal tubule reduces the delivery of solutes to the macula densa, effectively inhibiting tubuloglomerular feedback and adenosine-mediated vasoconstriction of the preglomerular (afferent) arteriole (Fig. 45.6).[156] The imbalance between pre- and postglomerular arteriolar resistance leads to development of glomerular hypertension and hyperfiltration.[115]

Mechanotransduction

Increased mechanical stress caused by glomerular hyperfiltration influences both glomerular and tubular structures. Stress-induced expansion of the GBM prompts adaptive podocyte hypertrophy and foot process effacement, ultimately resulting in denudement of areas of the GBM and podocyte detachment. Podocytes respond to mechanical stress by modifying the actin cytoskeleton and activating various signaling pathways, including protein kinases, prostaglandins, angiotensin II, mTOR, and transforming growth factor-β (TGF-β.) This property,

BOX 45.5 STRUCTURAL CHANGES OF THE KIDNEY IN DIABETIC KIDNEY DISEASE

- Structural changes in diabetic kidney disease (DKD) are similar in patients with type 1 diabetes mellitus and type 2 diabetes mellitus, but the pathological and clinical presentation is less predictable in type 2 diabetes mellitus.
- All kidney compartments display structural changes.
- The earliest changes are glomerular and tubular hypertrophy at the stage of glomerular hyperfiltration.
- Glomerular changes include glomerular basement membrane thickening, podocyte foot process effacement and detachment, mesangial expansion and formation of Kimmelstiel–Wilson nodules, and glomerulosclerosis.
- The tubulointerstitium develops fibrosis and inflammation and tubular atrophy.
- The arterioles display hyalinosis and arteriosclerosis.
- Structural changes may be present without clinically evident DKD.

known as "mechanotransduction," is now recognized as an important contributor to DKD pathogenesis.[157-160] Mechanotransduction also plays a role in tubulointerstitial injury, where increased shear stress on proximal tubule microvilli transmits to the brush border cytoskeleton. This process also signals activation of the luminal NHE3 transporter and the basolateral sodium-bicarbonate cotransporter to increase sodium reabsorption in the proximal tubule and thereby exacerbates glomerular hyperfiltration by decreasing distal sodium delivery and reducing tubuloglomerular feedback.[161-162]

Inflammation and Fibrosis

Activation of a network of inflammatory cells coexpressing markers specific for macrophages and dendritic interstitial cells, referred to as the renal mononuclear phagocyte system, precipitates the release of proinflammatory cytokines and paracrine signals in the diabetic kidney.[163-164] Proinflammatory cytokines, in turn, recruit additional monocytes and macrophages, perpetuating a vicious cycle of cytokine release and inflammatory cell recruitment.[165-168] The number of proinflammatory cells and cytokines correlates with DKD progression. The extent of glomerulosclerosis, tubulointerstitial inflammation, and rate of eGFR decline are correlated with macrophage infiltration.[169-170] Involvement of proinflammatory cytokines (e.g., interleukin [IL] 1, IL-6, IL-18, and tumor necrosis factor α) has been implicated in contributing to numerous DKD mechanisms, including oxidative stress, glomerular hemodynamics, recruitment and activation of inflammatory cells, extracellular matrix formation, GBM thickening, and podocyte and endothelial cell injury.[171-176] Similarly, chemokines and adhesion molecules, including MCP1/chemokine C-C motif-ligand 2, C-X3-C motif chemokine, and

BOX 45.6 PATHOPHYSIOLOGY OF DIABETIC KIDNEY DISEASE

- Metabolic, hemodynamic, inflammatory, fibrotic, and epigenetic changes in the diabetic milieu lead to structural and functional abnormalities of diabetic kidney disease (DKD).
- Increased glucose and sodium chloride uptake in the proximal tubule via sodium-glucose cotransporter 2 reduces solute delivery to the macula densa, resulting in decreased tubuloglomerular feedback and glomerular hyperfiltration.
- Glomerular hyperfiltration is the earliest hemodynamic change in DKD.
- Mechanotransduction, induced by mechanical stress from glomerular hyperfiltration, is a key contributor to DKD pathogenesis.
- Inflammatory and profibrotic mediators contribute to a variety of structural and functional changes involved in DKD development and progression.

Epigenetic Changes

Epigenetic changes constitute a plausible mechanism underlying damage to the diabetic kidney stemming from metabolic memory following exposure to persistent hyperglycemia. The epigenetic modifications most studied in the context of DKD include DNA methylation, histone modification, noncoding miRNAs, and long noncoding RNAs. DNA methylation may be involved in the pathogenesis and progression of DKD by regulating the expression of many genes impacting glomerular and tubular cell function.[46,180,181] Both in experimental mouse models and in biopsy studies of diabetic patients, histone modifications are associated with inflammation in podocytes and upregulation of profibrotic genes that promote kidney fibrosis. Fig. 45.6 Normal and diabetic nephron with altered renal hemodynamics. A, Afferent vasodilation is promoted by hyperglycemia, hyperinsulinemia, elevated level of circulating amino acids, COX-2 prostanoids, and reduction of tubule glomerular feedback. Tubuloglomerular feedback is a kidney intrinsic autoregulatory mechanism that helps regulate the rate of glomerular filtration. Because of increased reabsorption of glucose and sodium via sodium-glucose cotransporters in diabetes, sodium chloride delivery to macula densa cells of juxtaglomerular apparatus is decreased, resulting in lower production of adenosin and consequent relative vasodilation of afferent arteriolar. **B,** Efferent vasoconstriction is promoted by high local angiotensin II level, endothelin I, reactive oxygen species, and thromboxane A2. (From Alicic RZ, Neumiller JJ, Johnson EJ, et al. Sodium-glucose cotransporter 2 inhibition and diabetic kidney disease. *Diabetes.* 2019; 68:248–257.)

glomerulosclerosis, inflammation, and podocyte injury.[182,183] TGF-β–mediated upregulation of miR-192 in proximal tubule cells has been linked to fibrosis and lower eGFR in patients with DKD. In mouse models of DKD, miR-192 inhibition reduced fibrosis and proteinuria.[184-187]

KEY POINTS

- Functional and structural abnormalities of diabetic kidney disease are result of a complex, self-perpetuated process driven by metabolic, hemodynamic, inflammatory, fibrotic, and epigenetic changes associated with the diabetic milieu.

TREATMENT

Treatment of DKD is centered around a multifactorial approach to addressing modifiable DKD risk factors. Interventions include glycemic control, use of glucose-lowering therapies with proven kidney protective benefits, blood pressure control with use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), management of cardiovascular risk factors, and nutritional management. Current recommendations related to these treatment approaches will be discussed, as well as a brief review of novel therapies in the developmental pipeline and population health considerations

TABLE 45.3 Key American Diabetes Association Recommendations for the Management of Diabetic Kidney Disease

Treatment

- Optimize glucose control to reduce the risk or slow the progression of chronic kidney disease (CKD). (Level of evidence: **A**)
- For patients with type 2 diabetes mellitus and diabetic kidney disease, consider use of a sodium-glucose cotransporter 2 inhibitor in patients with an estimated glomerular filtration rate (eGFR) ≥30 mL/min/1.73 m^2 and urinary albumin >300 mg/g creatinine. (Level of evidence: **A**)
- In patients with type 2 diabetes and CKD, consider use of sodium-glucose cotransporter 2 inhibitors additionally for cardiovascular risk reduction when eGFR and UACR are ≥30 mL/min/1.73m^2 or >300 mg/g, respectively. (Level of evidence: **A**)
- In patients with CKD who are at increased risk for cardiovascular events, use of a glucagon-like peptide 1 receptor agonist reduces renal end point, primarily albuminuria, progression of albuminuria, and cardiovascular events. (Level of evidence: **A**)
- Optimize blood pressure control to reduce the risk or slow the progression of CKD. (Level of evidence: **A**)
- In nonpregnant patients with diabetes and hypertension, either an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker is recommended for those with modestly elevated urine albumin-to-creatinine ratio (UACR; 30–299 mg/g creatinine) (Level of evidence: **B**) and is strongly recommended for those with UACR ≥300 mg/g creatinine and/or eGFR <60 mL/min/1.73 m^2. (Level of evidence: **A**)

Referral

- Patients should be referred for evaluation by a nephrologist if they have an eGFR <30 mL/min/1.73 m^2. (Level of evidence: **A**)
- Promptly refer to a physician experienced in the care of kidney disease for uncertainty about the etiology of kidney disease, difficult management issues, and rapidly progressing kidney disease. (Level of evidence: **A**)

Recommendations are assigned evidence ratings per the ADA's evidence grading system.
(Modified from American Diabetes Association. Standards of Medical Care in Diabetes—2021. *Diabetes Care*. 2021; 44:S1–S232.)

for improving DKD outcomes. Table 45.3 provides a summary of key recommendations from the American Diabetes Association (ADA) for management of DKD (Box 45.7).[1]

Glycemic Control

Optimization of glycemic control to reduce risk or slow progression of DKD is considered the cornerstone of management.[1,91] Targeting lower HbA1c values through intensification of glucose-lowering therapy has shown benefit in reducing risk for development of diabetes complications, including DKD.[66,188-190] However, achieving therapeutic targets in the DKD population is challenged by reduced capacity for gluconeogenesis by the kidney and impaired clearance of glucose-lowering therapies, thus placing DKD patients at high risk for hypoglycemia or other adverse drug events.[88,133] The Kidney Disease: Improving Global Outcomes (KDIGO) 2020 Clinical Practice Guideline for Diabetes Management in CKD recommends a combination of metformin plus an SGLT-2 inhibitor as first-line pharmacotherapy in most patients with T2DM and CKD with an eGFR over 30 mL/min/1.73 m^2.[91] The addition of additional glucose-lowering agents, as needed, to achieve patient-specific glycemic goals is recommended, with a preference given to a long-acting agent from the GLP1 receptor agonist class.[91] Recommendations for use of agents from the SGLT-2 inhibitor and GLP1 receptor agonist classes are based on recent cardiovascular and kidney disease outcome trials demonstrating benefit with these agents.

Glycemic Monitoring. HbA1c is the recommended biomarker for long-term monitoring of glycemia in DKD.[1,91,133] The HbA1c value can be falsely decreased by factors that reduce the erythrocyte lifespan, such as anemia, red blood cell transfusion, and use of erythrocyte-stimulating agents or iron replacement, particularly in patients undergoing hemodialysis.[87,191,192] Conversely, HbA1c may be falsely increased by metabolic acidosis, carbamylation, and advanced glycation end product formation, which are common in advanced DKD stages. Nonetheless, HbA1c remains the biomarker of choice, as alternative methods such as fructosamine or glycated albumin do not have more accurate relationships to glycemia compared with HbA1c testing. Self-monitoring of blood glucose (SMBG) or continuous glucose monitoring (CGM) is additionally recommended to inform daily treatment decisions, especially in advanced DKD stages. SMBG and CGM are not biased by CKD and can be effective tools to validate HbA1c findings.[91] In patients for whom the reliability of the HbA1c is uncertain (advanced DKD stages or hemodialysis), CGM can be used to generate a glucose management indicator, a calculated measure of average glucose control, generated from CGM data to inform treatment decisions.[193]

Glycemic Targets. The 2020 KDIGO guideline for diabetes management in CKD recommends an individualized HbA1c target based on patient- and medication-specific factors target ranging from less than 6.5% to less than 8.0% in patients not treated with dialysis.[1,91] Targeting an HbA1c less than 6.5% may be appropriate in younger people with earlier DKD for whom prevention of additional complications is a major consideration, while a more liberal HbA1c target (e.g., <8.0%) may be more appropriate in those with longstanding diabetes and a high comorbidity burden or a high risk of hypoglycemia or hypoglycemia unawareness.[91] Table 45.4 provides a summary of factors to guide HbA1c target selection in patients with DKD.[1,91] When HbA1c may not be a reliable indicator of glycemic control in advanced DKD and use of CGM is an option, CGM metrics such as time in range and time spent in hypoglycemia (defined as time spent <70 mg/dL) may be helpful in guiding daily care and treatment modification.[91]

Glucose-Lowering Agents

The SGLT-2 inhibitor and GLP1 receptor agonist classes have demonstrated kidney- and heart-protective benefits extending beyond their impact on glycemia in large-scale clinical trials.

Sodium-Glucose Cotransporter 2 Inhibitors. The ADA and KDIGO clinical practice guidelines recommend addition of an SGLT-2 inhibitor in patients with CKD independent of the current HbA1c or individualized HbA1c target for patients with an eGFR greater than or equal to 30 mL/min/1.73 m^2.[1,91] The initial signal for a kidney-specific benefit of this medication class came from secondary outcomes reported in the cardiovascular outcome trials (CVOTs) with canagliflozin, dapagliflozin, and empagliflozin. All showed reduced risk of DKD onset and progression with the SGLT-2 inhibitors.[194-197] These findings prompted study of SGLT-2 inhibitors in patients with T2DM and CKD to determine the effects on kidney disease endpoints as primary outcomes (Table 45.5).[198,199] The Canagliflozin and Renal

BOX 45.7 TREATMENT OF DIABETIC KIDNEY DISEASE

Glycemic Control

- First-line therapy for patients with type 2 diabetes mellitus and chronic kidney disease with an estimated glomerular filtration rate >30 mL/min/1.73 m^2 is metformin plus a sodium-glucose cotransporter 2 inhibitor. For patients requiring additional glucose-lowering therapy, a long-acting glucagon-like peptide-1 receptor agonist is preferred.
- Glycated hemoglobin (HbA1c) is the recommended metric in diabetic kidney disease (DKD) for assessment of long-term glycemic control; however, limitations of HbA1c in this population reduces the reliability of this measurement.
- Self-monitoring of blood glucose and continuous glucose monitoring are recommended for glucose monitoring to inform daily self-management and prevent hypoglycemia.
- An individualized HbA1c target in the range of <6.5%–7.0% to <8.0% is recommended.

Blood Pressure Control

- A blood pressure target of <140/90 mm Hg is recommended for patients without albuminuria, while a more intensive target of <130/80 mm Hg is recommended for those with albuminuria.
- Angiotensin-converting enzyme (ACE) inhibitor/angiotensin receptor blocker (ARB) therapy at the highest approved and tolerated dose is recommended for patients with diabetes and albuminuria.
- Combination ACE inhibitor plus ARB therapy is not recommended, because of risks of hyperkalemia and acute kidney injury.

Cardiovascular Risk Reduction

- In addition to optimized blood pressure control, lifestyle interventions (nutrition management and physical activity), lipid management with a statin, smoking cessation, and guideline-directed antiplatelet therapy are recommended.

Nutritional Management

- Patients with DKD should be encouraged to adopt a generally healthy diet that stresses consumption of whole foods such as vegetables, fruits, whole grains, fiber, legumes, plant-based proteins, unsaturated fats, and nuts.
- Patients with DKD are recommended to maintain daily protein intake of 0.8 g/kg per day, with a higher daily protein intake of 1.0–1.2 g/kg per day recommended for those treated by dialysis.
- To assist with blood pressure management, patients with DKD are recommended to limit daily sodium consumption to <2 g/day.

Events in Diabetes with Established Nephropathy Clinical Evaluation enrolled participants with eGFR of 30 or higher and less than 90 mL/min/1.73 m^2 and UACR of 300 or higher and less than 5000 mg/g.[198] After a mean follow-up period of 2.6 years, the composite outcome inclusive of ESKD, doubling of serum creatinine, or death from kidney disease causes was lower in the intervention group (hazard ratio [HR]: 0.68; 95% confidence interval [CI]: 0.5–-0.81; $P < .001$). When analyzed alone, the relative risk of ESKD was lowered by 32% (HR: 0.68; 95% CI: 0.54–0.86; $P = .002$). Canagliflozin treatment was also shown to improve the cardiovascular composite outcomes of cardiovascular death or hospitalization for heart failure (HR: 0.69, 95% CI: 0.57–0.83; $P < .01$), and cardiovascular death, myocardial infarction, or stroke (HR: 0.80; 95% CI: 0.67–0.95; $P = .01$). The risk of hospitalization for heart failure was also reduced with intervention when compared with placebo (HR: 0.61; 95% CI: 0.47–0.80; $P < .001$).[198] Subsequently, the Dapagliflozin and Prevention of Adverse Outcomes in Chronic Kidney Disease enrolled patients with or without T2DM and with eGFR of 25 or more and less than 75 mL/min/1.73 m2 and UACR of 200 or more and less than 5000 mg/g.[199] The primary composite outcome of a sustained decline in eGFR of greater than 50%, ESKD, or death from kidney disease or cardiovascular causes was significantly reduced with dapagliflozin treatment (HR: 0.61; 95% CI: 0.51–0.72; $P < .001$).[199] Importantly, in both studies the benefit of SGLT-2 inhibitor treatment was on top of the standard of care with an ACE inhibitor or an ARB. The Cardiovascular and Renal Outcomes with Empagliflozin in Heart Failure (EMPEROR-Reduced) study enrolled diabetic and nondiabetic patients with heart failure and reduced systolic function. The risk of a primary outcome event was significantly reduced (HR for cardiovascular death or hospitalization for heart failure: 0.75; 95% CI: 0.65–0.86; $P < .001$) over a median of 16 months. The EMPEROR-Reduced study confirmed the beneficial effects of SGLT-2 inhibition on kidney function as the major secondary outcome. Independent of diabetes status, eGFR decline was significantly slower in participants treated with empagliflozin (–0.55 vs. –2.28 mL/min/1.73 m^2 per year in the intervention and placebo groups, respectively; $P < .001$). Empagliflozin-treated participants also had a 50% reduction in risk of kidney failure or requiring KRT (HR: 0.50; 95% CI: 0.32–0.77).[200] Although current guidelines recommend use of SGLT-2 inhibitors in appropriate patients to mitigate kidney risk, potential side effects and safety concerns with this class of medication must also be considered. Potential notable harms that have been associated with SGLT-2 inhibitor therapy include DKA and genital mycotic infections.[91] The

TABLE 45.4 Factors That May Guide Decisions on Individualized Glycated Hemoglobin Targets in Diabetic Kidney Disease

Factor/Consideration	Supports More Stringent HbA1c Target (e.g., <6.5% or 7.0%)	Supports Less Stringent HbA1c Target (e.g., <8.0%)
Chronic kidney disease (CKD) severity	Early-stage CKD (e.g., CKD G1)	Advanced-stage CKD (e.g., CKD G5)
Macrovascular complications	Absent/minor	Present/severe
Comorbidity burden	Low	High
Life expectancy	Long	Short
Hypoglycemia risk	Low	High
Hypoglycemia awareness	Present	Impaired
Resources/support	Available	Scarce
Patient motivation/preference for treatment intensity	Highly motivated	Low motivation

(Modified from Kidney Disease: Improving Global Outcomes (KDIGO) Diabetes Work Group. risk of DKA with SGLT-2 inhibitors is rare in patients with T2DM but educating patients and caregivers about reporting symptoms suggestive of DKA is warranted. Likewise, counseling patients about appropriate self-care and hygiene, such as daily bathing, can reduce the risk of genital mycotic infections.[91] Because an increased risk of lower-limb amputations was observed in one clinical trial with canagliflozin, encouraging patients to engage in routine preventative foot self-care and maintain adequate hydration may reduce the risk for lower extremity complications.[91]

A principal mechanism by which SGLT-2 inhibitors convey kidney protection is believed to be reduced glomerular hyperfiltration via restoration of solute delivery to the macula densa and reversal of vasodilation of the afferent arteriole by increased tubuloglomerular feedback (Fig. 45.7).[156] SGLT-2 inhibitors may also improve DKD risk factors such as hyperglycemia, obesity, and hypertension.[156] These agents have other pleiotropic protective effects, including: increased erythropoietin, red blood cell mass, and oxygen delivery; mild ketosis providing β-hydroxybutyrate as a myocardial fuel; reduction of inflammation and oxidative stress; and inhibition of sodium-hydrogen exchanger activity in the kidney and heart.[201]

Glucagon-Like Peptide-1 Receptor Agonists. GLP1 receptor agonists are effective glucose-lowering agents even in advanced stages of DKD. KDIGO preferentially recommends the addition of a long-acting GLP1 receptor agonist in patients with T2DM and CKD who need additional glucose lowering if first-line metformin plus an SGLT-2 inhibitor is insufficient to meet individualized glycemic goals.[91] To date, kidney disease outcomes data with agents from the GLP1 receptor agonist class are limited to secondary outcomes from the CVOTs and a glycemic control trial showing benefits on albuminuria onset and progression[202-204] and eGFR decline.[205] A metaanalysis of GLP1 receptor agonists evaluated a composite kidney disease outcome inclusive of development of macroalbuminuria, decline in eGFR or increase in creatinine, progression to kidney failure, or death owing to kidney disease.[206] GLP1 receptor agonist treatment was associated with a 17% relative risk reduction in the composite kidney outcome (HR: 0.83; 95% CI: 0.78–0.89; $P < .0001$), which was primarily attributed to a reduction in albuminuria.[206] Although current kidney disease outcome data is limited to secondary outcomes, the Effect of Semaglutide Versus Placebo on the Progression of Renal Impairment in Subjects With Type 2 Diabetes and Chronic Kidney Disease (FLOW) study is prospectively testing the impact of injectable semaglutide on kidney disease as primary outcomes in patients with DKD.[207] The FLOW trial will enroll approximately 3200 participants with T2DM with eGFR of 25 or more to less than75 mL/min/1.73 m^2 and UACR of 300 or more to less than 5000 mg/g.[207] The primary outcome is a composite of kidney disease endpoints (≥50% eGFR decline, kidney failure, and death from kidney disease or cardiovascular disease). This is the first trial to include kidney disease endpoints as the primary outcome with an agent from the GLP-1 receptor agonist class. In terms of adverse events, GLP1 receptor agonists are commonly associated with gastrointestinal (GI) side effects (e.g., nausea, vomiting, diarrhea) and injection site reactions, which can both vary by agent used.[91] GI side effects tend to abate with continued use; however, patients should be encouraged to contact their healthcare provider if severe GI side effects occur, and to maintain hydration. GLP1 receptor agonists are contraindicated and should not be initiated in patients with a history of medullary thyroid cancer, multiple endocrine neoplasia 2, or a history of acute pancreatitis.[91]

Experimental data suggest several mechanisms by which GLP1 receptor agonists may provide benefit in DKD. GLP1 receptor agonists may reduce both systemic and local inflammation as plausible mechanisms to confer kidney protective effects.[208] In preclinical models of diabetic rats and mice, GLP1 receptor agonists reduce pathological changes of inflammation and fibrosis, along with decreased proinflammatory and profibrotic mediators in the glomerular and tubulointerstitial compartments.[208]

Blood Pressure Control

Antihypertensive therapy reduces risks for of DKD and related cardiovascular events.[209] For those at lower risk for cardiovascular disease (10-year atherosclerotic cardiovascular disease [ASCVD] risk of <15%) a target blood pressure of less than 140/90 mm Hg is recommended by the ADA for patients with diabetes and hypertension.[1] For patients at higher risk (existing ASCVD or 10-year ASCVD risk ≥15%), a target of less than 130/80 mm Hg is appropriate if it can be achieved safely. These targets are in line with those recommended by KDIGO.[210] The preferred antihypertensive classes include ACE inhibitors, ARBs, dihydropyridine calcium channel blockers, and thiazide-like diuretics. In the presence of albuminuria, an ACE inhibitor or an ARB is specifically recommended.

TABLE 45.5 Summary of Completed Sodium-Glucose Cotransporter 2 Inhibitor Trials With Primary Outcomes for Kidney Disease

Agent	Canagliflozin	Dapagliflozin
Study	CREDENCE (n = 4,401)	DAPA-CKD (n = 4,304)
Median follow-up (years)	2.6	2.4
Kidney-related enrollment criteria†	• eGFR ≥30 to <90 mL/min/1.73 m^2 • UACR: ≥300 to <5000 mg/g	• eGFR ≥25 to <75 mL/min/1.73 m^2 • UACR: ≥200 to 5000 mg/g
Mean baseline eGFR	56 mL/min/1.73 m^2	43 mL/min/1.73 m^2
Median baseline UACR	927 mg/g	949 mg/g
Kidney outcome(s)	Primary Outcome • ESKD (dialysis, transplantation, or sustained eGFR <15 mL/min/1.73 m^2), doubling of SCr, or death from renal causes: HR: 0.70 (0.59–0.82)	Primary Outcome • ≥50% decrease in eGFR, ESKD, or death from renal or cardiovascular causes: HR: 0.61 (0.51–0.72)

eGFR, Estimated glomerular filtration rate; *ESKD*, end-stage kidney disease; *HR*: hazard ratio; *SCr*, serum creatinine; *UACR*, urinary albumin-to-creatinine ratio.

Fig. 45.7 **Effects of diabetes and SGLT2 inhibition on nephron hemodynamics. A:** Increased reabsorption of glucose by SGLT2 in the proximal convoluted tubule decreases delivery of solutes to the macula densa. The resulting decrease in ATP release from the basolateral membrane of tubular epithelial cells reduces production of adenosine and produces a vasodilatation of the afferent arteriole. **B:** SGLT2 inhibitors restore solute delivery to the macula densa with resulting adenosine activation and reversal of vasodilation of the afferent arteriole. (From Alicic RZ, Neumiller JJ, Johnson EJ, et al. Sodium-glucose cotransporter 2 inhibition and diabetic kidney disease. *Diabetes*. 2019; 68:248–257.)

Renin-Angiotensin-Aldosterone System Inhibitors. In patients with DKD and T1DM or T2DM, use of an ACE inhibitor or ARB reduces risk of progression to kidney failure.[211-213] Clinical practice guidelines consistently recommend treatment with an ACE inhibitor or an ARB in patients with diabetes, hypertension, and albuminuria at the highest tolerated dose approved for use by regulatory agencies.[1,91] Combination ACE inhibitor plus ARB therapy is not recommended, as there are no additive benefits on cardiovascular or kidney disease outcomes, and the combination was associated with higher risks for hyperkalemia and AKI.[214,215]

The effect of Finerenone, the nonsteroidal mineralcorticoid inhibitor, on kidney and cardiovascular outcomes in patients with moderate to severe DKD was studied in two large trails. The Finerenone in Reducing Cardiovascular Mortality and Morbidity in Diabetic Kidney Disease (FIGARO-DKD) and companion study the Effect of Finerenone on Chronic Kidney Disease Outcomes in Type 2 Diabetes (FIDELIO-DKD) trial enrolled participants with eGFR >25 to <75 ml/min/1.73 m^2 and a UACR >300 to <5000 mg/g or eGFR >25 to <60 ml/min/1.73 m^2 and a UACR >30 to <300 mg/g with retinopathy.[216,217] Compared with placebo, finerenone reduced the risk of the composite primary kidney disease outcome (kidney failure, a sustained decrease in eGFR of >40%, or death from kidney disease) by 18% (HR: 0.82; 95% CI: 0.73–0.93; *P* = .001). The key secondary composite outcome (death from cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, or hospitalization for heart failure) was also reduced (HR: 0.86; 95% CI: 0.75–0.99; *P* = .03). Participants in the finerenone and placebo groups experienced similar rates of kidney injury–related events. The rate of hyperkalemia-related events was twice as high in those receiving finerenone versus placebo (18.3% vs. 9.0%, respectively), indicating that potassium monitoring will be important in patients treated with this agent. In FIGARO-DKD, finerenone treatment was positive for the primary cardiovascular composite outcome inclusive of: death from cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, and hospitalization for heart failure (HR: 0.87; 95% CI: 0.76-0.98; P=0.03). Event rates for hyperkalemia were overall low in the trial (2.3% versus 0.9% in the finerenone and placebo groups, respectively).[216] FIGARO-DKD and FIDELIO-DKD outcomes supported FDA approval of finerenone for risk reduction of sustained eGFR decline, reaching end stage kidney disease, cardiovascular death, non-fatal myocardial infarction, and hospitalization for heart failure in adults with chronic kidney disease associated with T2DM.[218] Clinical practice guidelines from major professional organizations are expected to be updated to recommend finerenone for kidney and heart protection in T2DM.[216]

Cardiovascular Risk Reduction

In patients with diabetes, the presence of CKD accounts for most of the increased cardiovascular risk.[13,219] Higher albuminuria and lower eGFR are independently and additively associated with an increased risk for cardiovascular events, mortality, and all-cause death.[88,220] In the UKPDS study, the overall death rate was nearly 20% per year in participants who were either receiving KRT or had a blood creatinine greater than 2 mg/dL.[221]

The American College of Cardiology recommends that adults with T2DM with ASCVD, heart failure, or DKD receive treatment with an SGLT-2 inhibitor or GLP1 receptor agonist with proven cardiovascular benefit.[222] In addition, they and KDIGO recommend optimization of guideline-directed medical therapy inclusive of lifestyle intensification (nutrition management and physical activity), blood pressure control, lipid management with a statin, glycemic control, smoking cessation, and antiplatelet therapy.[91,222]

Nutrition Management

Key considerations include adopting a generally healthy and balanced diet, maintaining appropriate protein intake, and avoiding excessive sodium intake. Like other patients with diabetes, those with DKD benefit from individualized diets that stress consumption of whole foods such as vegetables, fruits, whole grains, fiber, legumes, plant-based proteins, unsaturated fats, and nuts.[1,91] Minimal consumption of processed meats, refined carbohydrates, and sweetened beverages is also encouraged. While dietary protein restriction has been hypothesized to slow DKD progression,[223] protein restriction combined with carbohydrate limitation can contribute to overly restrictive diets and weight loss.[91] KDIGO recommends following the World Health Organization recommendation of a protein intake of 0.8 g/kg per day, with an emphasis on plant-based sources for patients with DKD.[91] For those treated by dialysis, a higher daily protein intake of 1.0 to 1.2 g/kg per day is recommended to compensate for amino acid losses via the dialysate and a catabolic state. To address dietary approaches to blood pressure control, patients with DKD are recommended to limit sodium intake to less than 2 g per day.[91] Evidence suggests that adherence to nutritional recommendations is low overall in patients with CKD.[224] Therefore, engaging patients in shared decision-making for an individualized nutrition plan is critical, as is providing nutrition education and promoting healthy behavior change.

Additional Interventions and Management Approaches

Multiple novel therapeutics for DKD are under study. Given the gaps in care, population health initiatives aiming to improve awareness, identification, and management of DKD are essential.

Novel Therapeutics. Despite recent therapeutic progress, new DKD treatments are needed to reduce residual risk by targeting disease pathways that may not be addressed by available approaches. Promising targets and drug candidates under study include further study of finerenone in earlier stage DKD, endothelin A receptor antagonism (atrasentan), and antiinflammatory signaling pathways (baracitinib, selonsertib) (Table 45.6).[225]

Health Delivery. Given the serious health consequences of DKD, early identification and initiation of interventions to prevent disease onset and progression are imperative. Even though an established standard of care has been in place for nearly two decades, patients with DKD often receive suboptimal care, reflected underuse of ACE inhibitors/ARBs and overuse of potentially nephrotoxic agents (nonsteroidal antiinflammatory drugs and proton pump inhibitors).[226] Healthcare delivery approaches for increased DKD awareness and initiation of evidence-based therapies are critical to improving clinical outcomes. Interventions at both the patient and health-systems level are recommended for patient-centered care through a multidisciplinary approach (Table 45.7).[91]

TABLE 45.6 Novel Therapeutic Targets for the Treatment of Diabetic Kidney Disease

Medication Class	Mechanism/Target	Candidate Drug(s)
Nonsteroidal mineralocorticoid receptor (MR) antagonist	Antagonism potentially leads to: • Reversal of ischemia-related kidney damage • Reversal of oxidative stress • Correction of impaired nitric oxide synthesis • Attenuation of macrophage-induced kidney injury	Finerenone
Endothelin A receptor antagonist	Antagonism reduces proteinuria, kidney fibrosis, and inflammation	Astrasentan
Apoptosis signal-regulating kinase 1 inhibitor	Antagonism reduces epithelial cell injury and kidney fibrosis	Selonsertib
Janus kinase 1/2 inhibitor	Inhibition prevents activation of STATs and reduces IgG, IgM, IgA, and C-reactive protein	Baricitinib

Ig, Immunoglobulin; *STAT*, signal transducer and activator of transcription.

TABLE 45.7 Management Approach Recommendations for Patients With Diabetes and Chronic Kidney Disease

- Structured self-management educational programs are recommended in people with diabetes and chronic kidney disease.
- Health systems should consider implementing structured self-management programs that consider local context, cultures, and resource availability.
- Implementation of team-based, integrated care that is focused on risk evaluation and patient empowerment.
- Team-based care should incorporate care delivered by physicians and nonphysician providers (e.g., nurses, dietitians, pharmacists, healthcare assistants, community workers, and peer supporters).

(Modified from Kidney Disease: Improving Global Outcomes (KDIGO) Diabetes Work Group. KDIGO 2020 clinical practice guideline for diabetes management in chronic kidney disease. *Kidney Int.* 2020; 98:S1–S115.)

KEY POINTS

- For patients with type 2 diabetes mellitus and chronic kidney disease, the recommended glycated hemoglobin target is individualized in the range of <6.5%–7.0% to <8.0%. In patients with an estimated glomerular filtration rate >30 mL/min/1.73 m^2, the first-line therapy is metformin plus a sodium-glucose cotransporter 2 inhibitor. In patients with albuminuria, a more intensive blood pressure target of <130/80 mm Hg is recommended, and use of angiotensin-converting enzyme inhibitor/angiotensin receptor blocker therapy is recommended at the highest approved and tolerated dose.

SUMMARY AND FUTURE DIRECTIONS

In contrast to other diabetic complications, the burden of DKD has steadily increased worldwide. Despite available therapies, the residual risk of DKD progression to death and kidney failure is unacceptably high. Notably, DKD awareness among patients and providers is low, and adherence to recommended standard-of-care interventions is poor. Recent therapeutic modalities shown to improve DKD outcomes, such as SGLT-2 inhibitors, GLP1 receptor agonists, and finerenone, show great potential to reduce the enormous human and societal burden of DKD. Together with efforts to implement harmonized multidisciplinary care, quality of life and survival in DKD can be improved, while also striving to develop and deliver even more effective approaches for this high-risk population.

KEY POINTS

- Prevention of diabetic foot ulcers involves aggressive glycemic control, management of associated medical risk factors, periodic physical examination (including foot and vascular examination), and proper foot care and hygiene strategies.
- The goal of all foot care strategies (both medical and surgical) is to achieve complete closure of the "skin envelope" as quickly as possible while maintaining a functional, ambulatory foot.
- Vascular reconstruction has proven to be a safe and durable revascularization alternative in patients with diabetes and should be used to avoid ischemic diabetic foot complications and resulting limb amputations.

INTRODUCTION

Diabetic foot and vascular complications, including ulcers, infections, and amputations, continue to rise at an alarming rate, presenting an enormous challenge to providers, patients, and caretakers across the entire healthcare spectrum. In the United States, care of the lower extremity accounts for one-third of the annual direct costs for diabetes,[1-3] and the 5-year mortality rate following a major (proximal to ankle) lower extremity amputation (56.6%) is second only to that of lung cancer (80%).[4,5] Remarkably, lower extremity complications of diabetes now constitute a top ten global burden of disability based on criteria set by the World Health Organization.[6,7]

The lifetime risk of developing a foot ulcer in patients with diabetes is 34%,[1] and more than 50% of wounds become infected.[8] In fact, the most common diabetes-related complication leading to hospitalization and lower limb amputation is diabetic foot infection.[9-11] Indeed, seconds count, as every 1.2 seconds someone develops a diabetic foot ulcer (DFU), every 7 seconds around the world someone dies from diabetes, and every 20 seconds someone is amputated.[12]

As the economic, medical, and social impacts of diabetic foot and vascular complications grow, focused education and evidence-based treatment strategies are needed to increase awareness and standardize care in clinical practice. Many providers and health systems throughout the world have successfully adopted the recommended multidisciplinary approach to diabetic foot care. In addition, advances in research, innovation, and technology have shown great potential in preventing amputations and preserving limbs.

Management of diabetic foot complications requires a thorough understanding of the pathophysiology of the underlying disease, as well as a familiarity with the wide range of therapeutic options currently available. The goal of this chapter is to outline the current concepts of diabetic foot disease and the most effective treatment strategies for both medical and surgical management.

KEY POINTS

- Diabetic foot and vascular complications present an enormous challenge to providers, patients and caretakers across the entire healthcare spectrum. In the United States, care of the lower extremity accounts for one-third of the annual direct costs for diabetes. The 5-year mortality rate following a major (proximal to ankle) lower extremity amputation (56.6%) is second only to that of lung cancer (80%). Every 1.2 seconds someone develops a diabetic foot ulcer, every 7 seconds around the world someone dies from diabetes, and every 20 seconds someone is amputated.

PATHOPHYSIOLOGY

The epidemiology and pathophysiology of diabetes have been discussed in previous chapters, and the pathways that lead to major complications, including retinopathy, neuropathy, and nephropathy, exhibit many of the same underlying mechanisms as lower extremity complications. Although glycemic control is critical in diabetes management, it is simply not enough to prevent diabetic complications of the diabetic foot. Furthermore, it is important for clinicians to be aware of the so-called etiologic triad leading to diabetic foot complications (i.e., neuropathy, ischemia, and infection) and to recognize that these may occur in isolation, but more commonly occur in combination.

Neuropathy

Neuropathy that arises from diabetes is often multifactorial in that sensory, motor, and autonomic fibers may be affected. Sensory neuropathy affects the small-diameter pain and temperature fibers first, which can result in decreased sensation and greater susceptibility to injury caused by pressure-related microtrauma and other minor skin injuries. Motor neuropathy affects the longer fibers that innervate the foot, including intrinsic foot muscles and leg muscles. Atrophy, or muscle wasting, of the intrinsic foot muscles allows the strong flexor muscles to draw the toes into a "clawed" position, whereby new pressure points form along the toes and metatarsals. In addition, diminished joint mobility combined with increased rigidity from glycation of scleral proteins exacerbates the situation by altering the normal weight distribution on the foot. Lastly, autonomic neuropathy causes the skin to become dry through loss of sweat and apocrine gland function. The resulting dry, scaly skin can lead to cracks and fissures, thereby creating a portal of entry for bacteria. Additionally, patients with diabetes can have a blunted neuroinflammatory response and thus are missing a crucial component of the body's natural first-line defense against pathogens.[13]

Infection

Patients with diabetes typically have an altered response to infectious processes owing to defects in their host immune defense system.[14] Moreover, wound healing can be delayed in these patients as a result of abnormal cellular and inflammatory pathways involving fibroblasts, neutrophils, and advanced glycation end-products (AGEs). Glycation is a nonenzymatic chemical reaction whereby sulfhydryl protein linkages are replaced by glucose, causing impairment in normal cellular and tissue functions.[15] AGEs increase the stiffness of precapillary vessel walls and contribute to the development of diabetic microangiopathy.[16] Additionally, the presence of neuropathy and ischemia can potentiate the infectious process whereby the loss of protective sensation from neuropathy leads to unrecognized injury and secondary infection, and ischemia results in poor healing, blunts the inflammatory response, and may lead to inadequate tissue levels of antimicrobial agents.

Ischemia

Up to 50% of patients with diabetes and foot ulceration have concurrent peripheral artery disease (PAD).[8,17] Significant progress has been made in identifying the underlying cause of lower extremity ischemia in patients with diabetes, and results have challenged longstanding misconceptions. Thus, it is imperative that practitioners continue to reject the so-called "small-vessel disease" theory related to occlusions of the microcirculation, as espoused by a single histologic study in 1959,[18] and instead embrace the notion that ischemia results from both atherosclerotic macrovascular disease and microcirculatory dysfunction.[19] Patients with diabetes typically suffer from tibial and peroneal arterial disease with sparing of the foot arteries, especially the dorsalis pedis and its branches.

Research has demonstrated that diabetes causes structural and functional changes within the arteriolar and capillary systems, notably thickening of the basement membrane. However, despite thickening of the capillary basement membrane, there is no decrease in capillary luminal diameter.[20] A thickened membrane impairs leukocyte migration and hampers the normal hyperemic or vasodilatory response to injury, thus simultaneously increasing the susceptibility to injury while blunting the typical manifestations of such an injury.[21] Overall, this dysfunction of the microcirculation in diabetic patients creates a functionally ischemic foot despite conditions that would otherwise allow normal blood flow in healthy patients.

Besides causing specific structural changes in the microcirculation, diabetes causes an undesirable shift in the natural balance that exists between stress/ulceration and resistance to stress/ulceration. Thus, the diabetic foot is more prone to tissue injury from the repetitive low-intensity stress of normal weight bearing. The presence of neuropathy may necessitate revascularization under conditions of perfusion that would not require revascularization in the absence of neuropathy and is often described as neuroischemia. Because of the compromise caused by this neuroischemia, the diabetic foot requires even more perfusion than usual to resist ulceration and/or respond appropriately to injury.

Bone and Joint Abnormalities

As discussed previously, neuropathy plays an important role in the development of bone and joint abnormalities in patients with diabetes. These deformities lead to biomechanical changes and the formation of high-pressure areas, which increases the risk of ulceration (Fig. 46.1). Furthermore, changes in foot biomechanics, combined with limited joint mobility, may result in structural deformities, including hallux abducto valgus, claw- and hammertoes, and abnormalities of the metatarsophalangeal joints. Patients with hammertoes are vulnerable to even minor shoe trauma, and contracted toes cause increased retrograde pressure along the plantar metatarsals. In addition, irregular osseous changes and midfoot collapse owing to Charcot neuroarthropathy, as well as severe flatfoot, equinus, and other knee or back problems, may contribute to increased biomechanical stress encountered by the foot, worsen the degree of ulceration, and/or inhibit proper healing.[22]

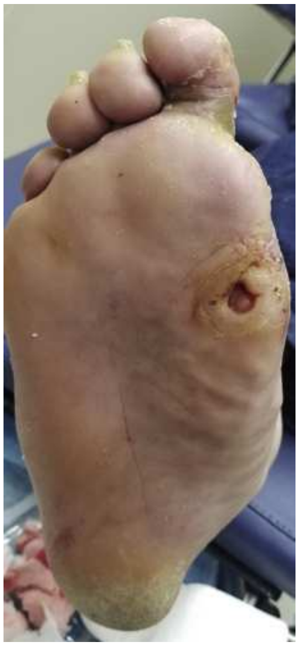

Fig. 46.1 Bone and joint abnormalities in the diabetic foot can result in the formation of high-pressure areas, increasing the risk of ulceration.

KEY POINTS

- It is important for clinicians to be aware of the so-called etiologic triad leading to diabetic foot complications (i.e., neuropathy, ischemia, and infection) and to recognize that these may occur in isolation, but more commonly occur in combination. Neuropathy that arises from diabetes is often multifactorial in that sensory, motor, and autonomic fibers may be affected. Patients with diabetes typically have an altered response to infectious processes owing to defects in their host immune defense system. Up to 50% of patients with diabetes and foot ulceration have concurrent peripheral artery disease. Bone and joint deformities in the foot lead to biomechanical changes and the formation of high-pressure areas, which increases the risk of ulceration.

PRESENTATION AND DIAGNOSIS

The mechanisms described previously place the diabetic patient at risk for lower extremity complications, ranging from simple ulcers to severe limb- or life-threatening infections and/or ischemic gangrene. As with most diseases, patient education and access to healthcare are integral to the timely diagnosis and treatment of these complications. Patients who are aware of their foot care needs are more likely to seek help during the early stages, and healthcare providers who regularly treat patients with diabetes are more likely to identify potential complications early. To decrease the morbidity and mortality associated with diabetic foot complications, healthcare providers must maintain heightened vigilance for these problems and execute appropriate judgment when making diagnoses in these patients.

Diabetic Foot Ulcers

Up to 25% of patients with diabetes will develop a foot ulcer during their lifetime,[23] of which one in five requires an amputation.[24] Many ulcers develop as a result of altered pressures created in the diabetic foot. These foot pressures are influenced by muscle atrophy, obesity, callus formation, other forms of local microtrauma (including improper footwear), and limited joint mobility. The presence of neuropathy, as discussed previously, increases the risk for ulcer formation, because patients with diabetes may not be aware of the damage they are inflicting on their feet through their normal activities of daily living. These patients are said to lack the “gift of pain,” and may develop severe complications rapidly.[25] Furthermore, impaired wound healing and blunted neuroinflammatory responses contribute to progression of the initial ulcer to a potentially more serious lesion.

Patients typically present with a wound that fails to heal or with pain at the site of a callus, pressure point, or other bony prominence. Important considerations for foot ulcers include the depth and extent of tissue loss, anatomic location, origin, presence of ischemia or infection, and clinical signs of systemic infection. Proper diagnosis of DFUs depends in large part on the education and reliability of the patient and physician. A patient must be instructed on the benefit of meticulous foot care and seek treatment regularly from a healthcare provider who is familiar with the diabetic foot. Similarly, the healthcare provider must be learned in the field of diabetes management so as not to miss the symptoms and signs of diabetic foot complications.

Infection/Osteomyelitis

As discussed earlier, patients with diabetes often have a blunted neuroinflammatory response and do not exhibit the typical physiologic reactions to infection. In fact, the usual manifestations of infection (e.g., fever, tachycardia, elevated white blood cell count) are frequently absent in diabetic patients. Therefore, patients with diabetes require extra vigilance so that providers do not underestimate potential limb- or even life-threatening conditions that may otherwise present as less severe. Unexplained hyperglycemia should prompt an aggressive search for an infectious source in patients with diabetes, as elevated glucose levels may be the only sign of impending problems.[26]

In many cases, patients do not recognize the signs of an infection until malodor or wound drainage becomes apparent on a shoe or sock (Fig. 46.2). By this point, the portal of entry for bacteria has already been well established, and a polymicrobial infection may overcome the diabetic patient’s defense system. It is therefore imperative that all ulcers or calluses be carefully probed and inspected, followed by unroofing of superficial eschar to search for potential deep space abscesses. It is not uncommon for clinicians to find unexpected purulent material or necrotic tissue underneath an area of dry crust or dry gangrene.

Deep abscess, osteomyelitis, and/or sepsis can develop rapidly in patients with diabetes. Diabetic foot infections are typically bacterial, and can be monomicrobial or polymicrobial, with *Staphylococcus* and *Streptococcus* representing the most common infecting organisms.[27,28] In patients with diabetes, osteomyelitis has been identified in up to 20% of outpatient cases and 67% of hospitalized patients requiring an amputation.[24,29] The majority of cases of osteomyelitis in the diabetic foot are the result of contiguous spread, with the ulcer forming the initial entry site of infection. Therefore, treatment of an acute infection may include antibiotics and surgery, depending on the severity and depth. Broad-spectrum empiric antibiotic therapy is started initially, followed by targeted therapy based on deep intraoperative tissue and bone cultures and sensitivities. Many times, multiple trips to the operating room are required before a wound is considered clean and uninfected. Once the wound is determined to be free of infection, planning of definitive procedures for closure can begin.

Although advanced imaging modalities can be helpful in diagnosing osteomyelitis, there may be significant costs associated with these tests, whereas the use of a simple metal probe may be sufficient in many cases. Grayson and coworkers revealed that, if a sterile probe hits bone, then osteomyelitis can be diagnosed with a sensitivity of 66%, a specificity of 85%, and a positive predictive value of 89%.[30]

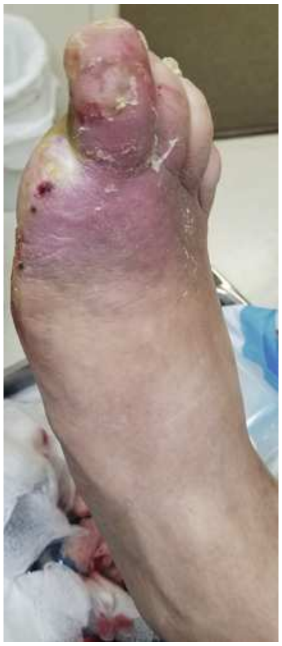

Fig. 46.2 Diabetic foot infection is often unrecognized until malodor or wound drainage becomes apparent on a patient’s shoe or sock.

Plain radiographs should be initially obtained to determine the extent of osseous erosion, as well as to assess anatomy for surgical planning.

Further advanced imaging with magnetic resonance imaging, computerized tomography scan, bone scintigraphy, or tagged white blood cell scan should be reserved for cases in which the metal probe test is equivocal, when an abscess or multifocal disease is suspected, or in patients with neuropathic osteoarthropathy, or Charcot's foot, in whom associated bony changes and inflammatory response can be misinterpreted as osteomyelitis. Definitive diagnosis of osteomyelitis is typically obtained by bone biopsy and deep intraoperative bone culture, but controversy exists regarding the consistency and validity of this approach.[31]

Peripheral Arterial Disease

The clinical presentation of peripheral arterial disease encompasses intermittent claudication, rest pain, and tissue loss (ulceration) with or without gangrene. The extent of ischemia and symptoms depends on the location of the vascular lesion, as well as the effectiveness of collateral circulation. Intermittent claudication presents as cramping, pain, or fatigue in the leg muscles, is seen with walking, and is relieved by rest. Of note, the anatomic location of the occlusive arterial lesion is usually one level above the clinically affected muscle group. Typically, aortoiliac disease causes buttock and thigh pain, and femoral disease causes calf discomfort. Tibial/peroneal disease usually does not cause claudication, although some patients will complain of foot pain or numbness while walking. Nocturnal muscle cramping, on the other hand, is a common complaint in diabetic patients and should not be mistaken for intermittent claudication, which results from exertion and is relieved by rest. Although claudication does cause disability from pain with walking, it rarely progresses to limb-threatening ischemia and often responds to conservative measures such as supervised exercise training[32] and smoking cessation.

Patients with more severe vascular disease may present with ischemic rest pain, which typically occurs in the distal foot and particularly the toes. Rest pain is exacerbated by recumbency and is relieved by dependency. Patients usually report pain when lying in bed or resting that is relieved by standing up and walking around. Diabetic neuropathy may sometimes mask symptoms of claudication or rest pain because these patients have blunted sensation in their lower extremities. More severe disease will result in tissue loss, including a foot ulceration or gangrene.

Once infection is ruled out, it is important to assess foot perfusion. Clinical examination alone is often insufficient in ruling out ischemia in patients with diabetes, and further investigation, such as ankle-brachial index (ABI), toe pressures, or skin perfusion pressure, may be warranted.[33] However, caution must be exercised in interpreting ABI results because of medial calcification, which is common in diabetes and can produce a falsely elevated or normal result.[34,35] Therefore, toe waveforms and systolic pressures are the preferred tests for patients with diabetes.

More recently, the Wound, Ischemia, and foot Infection (WIfI) classification has emerged as a valuable tool in evaluating patients at risk for limb loss. The WIfI system, based on wound depth, infection, and perfusion status, incorporates several other classification systems. Furthermore, it provides a comprehensive stratification model for determining amputation risk and aids in clinical decision-making.[36] It is critical that impaired perfusion be diagnosed promptly and staged based on the Society for Vascular Surgery WIfI classification. For example, WIfI stage 3 and 4 patients most often benefit from revascularization, and these patients should be identified early and treated aggressively. Any delay can result in loss of tissue and reduce the opportunity for limb preservation.[36,37] In addition to measuring wound characteristics, ischemia, and foot infection, functional deficit is now being added as a secondary survey after initial assessment of limb threat.[38] The WIfI plus Functional Impairment classification of limb threat is shown in Fig. 46.3.[36,38,39]

KEY POINTS

- Up to 25% of patients with diabetes will develop a foot ulcer during their lifetime, of which one in five requires an amputation. Impaired wound healing and blunted neuroinflammatory responses contribute to progression of the initial ulcer to a potentially more serious lesion. The usual manifestations of infection (e.g., fever, tachycardia, elevated white blood cell count) are frequently absent in diabetic patients. More recently, the Wound, Ischemia, and foot Infection (WIfI) classification has emerged as a valuable tool for evaluating patients at risk for limb loss. The WIfI system is based on wound depth, infection, and perfusion status and incorporates several other classification systems.

MEDICAL MANAGEMENT

In addition to wound healing, the goals of diabetic foot management include infection control, amputation prevention, maintenance of health status, improved function and quality of life, and reduced costs.[40] Numerous modalities are available for achieving these goals, and healthcare providers who treat diabetic patients should be familiar with the most current therapeutic options.

Prevention and Screening

International guidelines suggest screening people at low risk for ulceration annually for loss of protective sensation and PAD, and persons at higher risk at higher frequencies for additional risk factors. For foot ulcer prevention, providers should educate patients about appropriate foot self-care and treat any preulcerative sign on the foot. Furthermore, moderate- to high-risk patients should be instructed to wear accommodative, properly fitting therapeutic footwear and consider monitoring foot skin temperature. Therapeutic footwear that has a demonstrated plantar pressure-relieving effect during walking to prevent plantar foot ulcer recurrence should be prescribed in higher risk patients.[41]

More specifically, prevention involves aggressive glycemic control; management of associated risk factors (such as smoking, hypertension, hyperlipidemia, and obesity); periodic physical examination, including a vascular examination; and perhaps most important, proper foot care and hygiene strategies. The importance of daily foot inspections should be emphasized to patients and their caretakers, with careful attention paid to calluses, fissures, and red or bruised areas, as well as open sores or blisters. Moisturizing creams should be used on dry areas of skin, and antifungal medication should be used as needed. In general, astringents and heat soaks should be avoided, as should patients' self-removal of eschar or other foot lesions. Toenails should be trimmed periodically to prevent penetration into adjacent toes and ulceration, in the hope that vigilance will prevent future complications.

Determining which patients are at risk for foot infection because of both neuropathy and ischemia is an important aspect of prevention.[23] Use of Semmes–Weinstein monofilament testing for sensory neuropathy and periodic vascular assessments (with or without the noninvasive vascular laboratory) are useful adjuncts in preventing foot complications.[42] The Ipswich touch test is a simplified sensory test that involves lightly touching the tips of the first, third, and fifth toes.[43]

Antibiotics

When DFUs become infected, deep (preferably, intraoperative) cultures should be obtained, and antibiotic therapy should be initiated. Common infective organisms include *Staphylococcus aureus, Streptococcus,* and occasionally gram-negative bacilli, and deeper infections may be polymicrobial, involving anaerobes and certain gas-forming species.[44] Initially, selection of broad-spectrum antibiotics should cover the most likely offending organisms and can be narrowed once gram stain or culture/sensitivity results have been reported. Other factors to bear in mind include local bacterial resistance patterns in a specific hospital or community, individual patient characteristics (such as comorbidities and allergies), and, most important, the severity of infection. Traditional therapy for osteomyelitis has been typically accepted as 4 to 6 weeks of intravenous antibiotics,[45] but recent studies have documented a greater than 30% recurrence rate using this modality alone.[46]

Wound Care

Local wound care is important to ensure adequate healing of DFUs, as well as to combat infection and prevent further complications. Debridement is an essential component of local wound care and many times can be performed at the bedside without anesthesia because of the neuropathy associated with diabetes. Debridement may take numerous forms, including mechanical, autolytic, enzymatic, and sharp. Mechanical debridement can involve various dressing types that remove adherent necrotic tissue, but is nonselective and can damage fragile tissue, whereas autolytic debridement depends on the patient's immune response and circulation, involves moist dressings, and is slow. Enzymatic debridement is selective for necrotic tissue and is achieved using commercial agents with various enzymes (such as collagenases). Lastly, sharp (surgical) debridement involves excision of tissue at the bedside or in the operating room.

The best wound care strategy combines sharp surgical debridement with a dressing type that effectively absorbs drainage and exudate while maintaining a moist wound environment. Numerous advanced wound-care modalities exist, such as negative pressure wound therapy (NPWT), cellular and tissue-based products, and hyperbaric oxygen therapy. Each has its own merits, but providers should be mindful of the economic implications and reimbursement challenges involved with using these dressings. Most importantly, any new wound-care modality should be regarded as adjunctive to frequent clinical examinations, high-quality local wound care, and offloading.

Prospective, randomized studies have demonstrated the effectiveness of NPWT in the treatment of DFUs.[47,48] In addition to maintaining a moist wound-healing environment, NPWT has been shown to decrease wound margins and promote granulation tissue formation and perfusion in DFUs. Furthermore, the mechanical stimulation of a wound by NPWT contributes to improved wound healing through micro- and macrostrain properties, and NPWT facilitates the removal of exudate and infectious materials.[49]

NPWT involves the application of local, subatmospheric pressure to a wound. Typically, a foam or gauze interface is applied directly to the wound site and connected to a pump via external tubing. The wound interface is secured in place with an adhesive dressing. A pressure of 75 to 125 mm Hg is commonly used, in a continuous or intermittent fashion, and can be adjusted based on the needs of the patient and healthcare team. Other uses include NPWT with fluid installation, closed-incision NPWT for complex, at-risk surgical sites, and ultraportable NPWT systems for skin graft bolstering.[50]

Offloading

Patients with diabetes and peripheral neuropathy are said to lack the "gift of pain," owing to decreased sensation and an inability to perceive emerging foot complications.[25] In addition, many patients do not adhere to recommendations for offloading, including protected weight-bearing (i.e., cast, boot), decreased activity level, and other preventative measures.

The "gold-standard" for offloading foot ulcers in patients with diabetes is total contact casting (TCC), and there is a large body of evidence in the literature to support its use. TCC can reduce pressure by up to 84% to 92% at the site of an ulcer and has been reported to heal most DFUs within 6 to 8 weeks.[51] Furthermore, Bus et al.[52] found that nonremovable offloading, that is, TCC, is more effective than removable devices for healing neuropathic foot ulcers. Yet, for all the evidence supporting the use of TCC for the treatment of DFUs, it is seldom used in practice. In a large multicenter study conducted by Wu and colleagues,[53] it was determined that, among 895 centers involved in the active treatment of DFUs, only 1.7% used TCC for the majority of cases. Several factors were noted to contribute to the lack of use of TCC, including patient tolerance, time needed to apply and remove the cast, materials cost, and reimbursement challenges.

One of the most important attributes of TCC is to ensure proper patient adherence because of its irremovability,[54] whereas removable cast walkers (RCWs), which allow for more frequent wound and skin inspection and dressing application, and, in some cases, provide nearly as much pressure reduction as TCC, are not as effective at healing DFUs.[55,56] A proposed alternative, the instant total contact cast (iTCC), has demonstrated healing results equivalent to TCC and may be more tolerable to patients. The iTCC consists of an RCW wrapped with cohesive bandage or fiberglass, rendering the device irremovable.[57]

KEY POINTS

- In addition to wound healing, the goals of diabetic foot management include infection control, amputation prevention, maintenance of health status, improvement of function and quality of life, and reduction in costs. For foot ulcer prevention, providers should educate patients about appropriate foot self-care and treat any preulcerative sign on the foot. Moderate- to high-risk patients should be instructed to wear accommodative, properly fitting therapeutic footwear and consider monitoring foot skin temperature. When diabetic foot ulcers become infected, deep (preferably intraoperative) cultures should be obtained, and antibiotic therapy should be initiated. Debridement is an essential component of local wound care and many times can be performed at the bedside without anesthesia because of the neuropathy associated with diabetes. The "gold-standard" for offloading foot ulcers in patients with diabetes is total contact casting.

SURGICAL MANAGEMENT

The goal of all foot care strategies is to achieve complete healing of the "skin envelope" as quickly as possible while maintaining a functional walking foot. When medical management is not enough, different surgical management strategies are available to treat the diabetic foot. These strategies range from wide debridement and drainage procedures to arterial reconstruction or amputation. The decision to operate necessitates careful preoperative planning by the surgeon, as well as a cooperative patient who is willing to accept the inherent risks of the procedure and the demanding rehabilitation period.

Drainage Procedures

When minor debridement strategies do not effectively relieve severe infection, it becomes imperative to perform more extensive drainage procedures (including partial open toe, ray, or forefoot amputation) to drain abscesses or remove necrotic tissue.[58] In fact, hidden infection should be suspected in any situation in which a well-perfused foot continues to experience necrosis. Adequate drainage should be obtained, even if foot function must be compromised initially, because function potentially can be restored later with numerous advanced wound-closure techniques; however, persistent infection can lead to severe limb- and life-threatening complications. Additionally, if ischemia appears to be contributing to the infection, then arteriography should be performed to determine whether perfusion is adequate, or if revascularization is necessary. Controlling active, spreading infection may delay revascularization initially, but longer waiting periods taken on in the hope of completely sterilizing wounds are not appropriate and may result in continued necrosis or tissue loss.[59] In fact, in some cases, inadequate blood flow may prevent the delivery of antibiotics, nutrients, or oxygen to the foot wound, thus requiring revascularization to correct the problem. Furthermore, bypass procedures can be performed safely in the presence of foot infection as long as sepsis has been controlled before surgery.[60]

Lower Extremity Arterial Reconstruction

Despite many preconceived notions that practitioners have about diabetic patients, research has shown that these patients usually tolerate revascularization extremely well and do not suffer from increased mortality or diminished graft patency.[61] The ultimate goal of any revascularization procedure should be to restore adequate perfusion distal to an occlusion to relieve symptoms and promote healing. The outflow target artery, or the site of the distal anastomosis, should be free of occlusive disease and should be in direct continuity with the arteries of the foot. Appropriate inflow and outflow vessels can be identified for revascularization via arteriography, including images of the pedal arteries. Selection of the appropriate conduit for the arterial reconstruction should be autologous vein because of superior patency rates compared with prosthetic grafts.[62] The decision to use saphenous vein in the reversed (*in situ*) or nonreversed position, as well as contralateral saphenous vein or arm vein when necessary, depends on the specific clinical circumstances and patient anatomy.

Occasionally, patients with diabetes may require reconstruction of the aortoiliac segment or will have disease limited to the superficial femoral artery above the knee, and in these cases prosthetic grafts are well suited to achieve this goal. However, because diabetic patients typically suffer from tibial and peroneal disease, the most effective bypass often involves restoring blood flow to the dorsalis pedis artery or the posterior tibial artery at the ankle using an autologous vein as the conduit.[61] Numerous reports have demonstrated the durability and success of distal origin grafts that obtain inflow from the popliteal artery and bypass over a shorter length to the arteries in the foot.[63,64] Although distal bypasses are technically challenging, success is attainable, especially when the surgeon maintains a flexible approach to preparation and placement of the vein graft.[65]

In one of the most comprehensive studies regarding dorsalis pedis revascularization in diabetic patients, Pomposelli and coworkers[66] reported results from more than 1000 bypasses spanning a decade. Primary patency, secondary patency, and limb salvage rates were 56.8%, 62.7%, and 78.2%, respectively, at 5 years, and 37.7%, 41.7%, and 57.7%, respectively, at 10 years. Patient survival was 48.6% and 23.8% at 5 and 10 years, respectively, and perioperative mortality was only 0.9%. The popliteal artery was the source of inflow in 53.2% of patients. Overall, pedal arterial reconstruction has proved to be a safe and durable revascularization alternative in diabetic patients and should be used to avoid ischemic diabetic foot complications.

Endovascular Procedures

Although surgical reconstruction remains the current gold standard for diabetic foot revascularization, recent advances in technology have allowed endovascular interventions to become integrated into the management strategies employed by vascular surgeons and interventionists. Research has definitively shown that balloon angioplasty and stenting are well suited to focal, short-segment iliac stenoses or occlusions, which exist in 10% to 20% of patients with diabetes.[67] Percutaneous intervention can be performed easily in the same setting as the preoperative diagnostic arteriogram.

Regarding outflow bypass procedures, the morbidity of open surgery can be quite significant and is not limited simply to local wound complications or myocardial infarctions. Readmission rates, reoperation, slow time to healing,[68] and time spent in rehabilitation must be factored into the risk-benefit analysis.[69] Nicoloff and colleagues[70] determined that the so-called "ideal outcome" (patent graft, healed wound, no additional operations in a fully ambulatory patient who can sustain independent living) was attainable only 14% to 22% of the time. When the potential pitfalls accompanying traditional surgical approaches to limb salvage are factored in, as well as the overall poor health and life expectancy of patients with peripheral vascular disease, less invasive endovascular therapy can represent a very attractive alternative.

Unfortunately, the literature supporting endovascular interventions consists mainly of individual case series and retrospective reviews and does not compare with the research describing traditional open bypasses. The Transatlantic Inter-Society Consensus Working Group restratified femoropopliteal and tibial lesions in 2007[67] and made recommendations for therapy based on lesion type (stenosis vs. occlusion), location, and length. Although the literature relating to endovascular interventions for critical limb ischemia is mixed in terms of positive and negative results,[71,72] the best and most recent scientific attempt to compare open and endovascular interventions was the Bypass Versus Angioplasty in Severe Ischemia of the Leg trial.[73] Although only 42% of the patients in this trial were known to have diabetes, the level of ischemia was comparable with the typical disease patterns seen in this patient population. Overall, the trialists concluded that, although the strategies are roughly equivalent at medium-term follow-up with regard to mortality and amputation-free survival, angioplasty should be used first for patients with significant comorbidities and with a life expectancy of less than 1 to 2 years, and bypass first for patients expected to live longer than 2 years. Longer follow-up from this trial will continue to provide statistically guided information in the years to come.

Amputations

When efforts at limb preservation prove unsuccessful, or if a situation becomes life-threatening, amputation must be considered. Minor amputations of toes, or transmetatarsal amputation, is practical after infection control and revascularization have been achieved. For cases in which the extent of tissue loss precludes a functional foot, when there are nonhealing wounds in the setting of patent grafts, and for control of sepsis, amputation below the knee is sometimes necessary. Surgeons should always strive to preserve the knee joint because of its functional significance in a patient's potential for rehabilitation. Above-the-knee amputations are reserved for debilitated patients with severe tissue loss or with no capacity to ambulate. Overall, because of modern advances in prostheses coupled with aggressive approaches to rehabilitation, amputation should be viewed as an acceptable modality to treat diabetic foot complications, and not as a treatment failure.

KEY POINTS

- The goal of all foot care strategies is to achieve complete healing of the "skin envelope" as quickly as possible while maintaining a functional walking foot. When medical management is not enough, different surgical management strategies are available to treat the diabetic foot. These strategies range from wide debridement and drainage procedures to arterial reconstruction or amputation. When efforts at limb preservation prove unsuccessful, or if a situation becomes life-threatening, amputation must be considered.

MULTIDISCIPLINARY APPROACH

As geographic and demographic differences persist in the delivery of care for patients at high risk for amputation,[74] a standardized, evidence-based approach is needed. A multidisciplinary approach to limb preservation has been repeatedly shown to reduce amputations,[75-79] with a growing number of national and international bodies supporting the establishment of these teams.[80,81] Because no one specialist possesses all the skills necessary for managing complex diabetic foot and vascular patients, a team of specialists with the required skills is necessary. For a multidisciplinary program to succeed, there must be a coordinated effort of physicians, including podiatric and vascular surgeons, nurses, allied health professionals, and administrators dedicated to the common goal of preserving functional limbs.

FUTURE TRENDS

Future trends in diabetic foot and vascular care must focus on the organization and integration of care, with an emphasis placed on identifying key points in healing and potential warning signs of impending recurrence. Technology that is portable, durable, automated, intelligent, ubiquitous, integrable, and affordable will have a significant impact on wound diagnostics and prevention programs.[49,82]

Recent advances in technology, including remote temperature monitoring (RTM), pressure monitoring and wearable technologies, have the potential to fundamentally change the management of patients with diabetes. One example is the Podimetrics RTM system (Podimetrics, Inc., Somerville, MA), which uses a wireless floor mat to record thermograms and detect temperature asymmetry that can be predictive of skin ulceration (Fig. 46.4). In a multicenter trial evaluating 129 participants with diabetes and history of DFU, the RTM system detected 97% of observed DFUs nearly 6 weeks before the clinical appearance of an ulcer. Of note, 86% of the study cohort used the system at least 3 days per week on average during the study.[83]

Another multicenter study found a significant decrease in resource utilization within a large integrated healthcare system using the RTM system. The authors reported a significant reduction in inpatient admissions, emergency room visits, incidence of ulcer recurrence, and amputations for patients who participated in a prevention program with RTM.[84] Further studies investigating the usefulness and practicality of remote and wearable technologies for the treatment of diabetic foot and vascular complications are needed.

KEY POINTS

- Future trends in diabetic foot and vascular care must focus on the organization and integration of care, with an emphasis placed on identifying key points in healing and potential warning signs of impending recurrence. Technology that is portable, durable, automated, intelligent, ubiquitous, integrable, and affordable will have a significant impact on wound diagnostics and prevention programs.

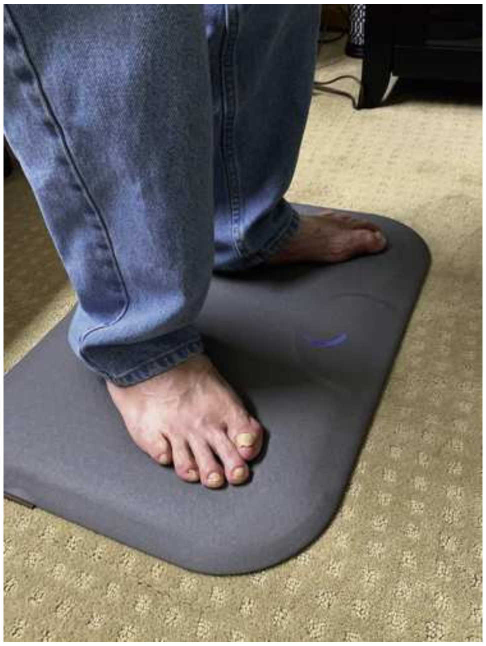

Fig. 46.4 Recent advances in technology, including a wireless remote temperature monitoring smart mat, have the potential to transform the way in which patients at high risk for diabetic foot complications are managed in the future.

Summary, 815

Parathyroid hormone (PTH) and PTH-related peptide (PTHrP), along with other calciotropic hormones, play critical roles in calcium and bone biology. First discovered as a calcium-regulating hormone in the 1920s, PTH is secreted by the parathyroid glands and is one of the most important regulators of blood calcium concentration in all terrestrial vertebrate species from amphibians to mammals. PTH is produced by discrete endocrine glands. In contrast, PTHrP is produced as a paracrine/autocrine factor in many different adult and fetal tissues and, unlike PTH, has multiple functions (see Chapter 48).

PTH and PTHrP most likely evolved from a common ancestral precursor. Despite this common evolutionary origin, both peptides share only limited overall amino acid sequence identity, yet their N-terminal regions are sufficiently homologous to enable them to bind to and activate a common G protein–coupled receptor (GPCR), the PTH/PTHrP receptor (also referred to as PTHR-1). This chapter reviews (1) the comparative chemistry of PTH, the structure of its gene, and the key elements of function within the hormone; (2) the evolutionary history of the PTH family of ligands, as well as the PTH receptor; (3) the role of PTH in calcium and phosphate homeostasis and in bone turnover; (4) new molecular structures obtained for the PTHR-1 and conformational changes involved in ligand-induced activation; (5) disease-causing mutations in the PTH receptor and ligands; and (6) the PTH receptor type-2 and its ligand, TIP39.

REGULATION OF MINERAL ION HOMEOSTASIS—GENERAL CONSIDERATIONS

To ensure a multitude of essential cellular functions, the concentration of extracellular calcium ion ($Ca^{2+}{}_o$) is maintained within a narrow range. In terrestrial vertebrates, calcium is necessary for adequate mineralization of the skeleton, which provides mechanical support and protection for internal organs and acts as levers for the various muscle groups involved in locomotion. Because of its high calcium content, representing 99% of the body's supply, the skeleton also serves as the most important reservoir from which calcium can be rapidly mobilized. Because food intake, and thus the nutritional supply of calcium, is usually discontinuous, intestinal calcium absorption occurs only intermittently. Maintenance of a constant blood calcium concentration thus constitutes a major homeostatic challenge, which led during evolution to the development of highly efficient mechanisms to increase intestinal calcium absorption, reduce urinary calcium losses, and facilitate, if necessary, rapid mobilization of calcium from the skeletal reservoir (see Chapter 52).

Unlike most terrestrial vertebrates, marine animals are usually exposed to the high environmental calcium concentration of seawater (10 mM) and thus had to adopt mechanisms by which $Ca^{2+}{}_o$ could be reduced. In contrast, both terrestrial and marine animals had to develop efficient mechanisms to enhance intestinal phosphate absorption and to prevent urinary losses of this essential mineral, leading in the mammalian kidney to an impressive capacity to retain phosphate. To reduce blood calcium concentrations, fish use stanniocalcin, which is produced by the corpuscles of Stannius, as well as several other hormonal factors. A putative mammalian homolog of stanniocalcin has shown similar properties when tested in rodents, but it remains uncertain whether this peptide hormone has a significant physiologic role in mammalian mineral ion homeostasis. The corpuscles of Stannius are located adjacent to the pronephros, and are furthermore the only tissue in fish expressing fibroblast growth factor 23 (FGF23), which is a major regulator of phosphate homeostasis in mammals.[1-3] Current data (see later) indicate that FGF23, the FGF23 coreceptor Klotho, dentin matrix protein 1, ecto-nucleotide pyrophosphatase/phosphodiesterase 1, and matrix extracellular phosphoglycoprotein are more likely to be involved physiologically in the regulation of mammalian phosphate homeostasis (see Chapter 53).

PARATHYROID HORMONE

PTH and the active form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) are the principal physiologic regulators of calcium homeostasis in humans and all terrestrial vertebrates. Synthesis and secretion of PTH are stimulated by any decrease in blood calcium, and, conversely, secretion of the hormone is inhibited by an increase in blood calcium. This rapid negative feedback regulation of PTH production, along with the biologic actions of the hormone on different target tissues, represents the most important homeostatic mechanism for the minute-to-minute control of calcium concentration in the extracellular fluid (ECF). The vital importance of PTH in maintaining calcium homeostasis and the rapid effects of PTH on blood levels of calcium, as well as phosphorous, are illustrated by the experiments performed in rats shown in Fig. 47.1.

In contrast to the rapid actions of PTH, $1,25(OH)_2D$ is of critical importance for long-term, day-to-day, and week-to-week calcium balance (see Chapter 50). The actions of both hormones are coordinated, and each influences the synthesis and secretion of the other. Calcitonin, the third of the calciotropic hormones known to be important in the regulation of vertebrate mineral ion homeostasis (see Chapter 49), may be vestigial in humans with respect to calcium homeostasis and will not be discussed in this brief review of physiology.

At least three distinct, but coordinated, actions of PTH increase the flow of calcium into the ECF and thus increase the concentration of blood calcium. Through its rapid actions on kidney and bone, which are all mediated through the PTHR-1 and subsequent secondary message molecules, such as cyclic 3′,5′-adenosine monophosphate (cAMP), that are activated in specific and highly specialized cells, PTH increases the release of calcium from bone, reduces the renal clearance of calcium, and stimulates the production of $1,25(OH)_2D$ by activating the gene encoding 25-hydroxyvitamin D-1α-hydroxylase (1α-hydroxylase) in the kidney. The relative importance of the first two actions of PTH on the rapid, minute-to-minute regulation of calcium is not definitively resolved, but most physiologists have stressed the importance of the effects of PTH on bone in maintaining hour-to-hour calcium homeostasis in the ECF. Several lines of evidence, such as that provided by calcium kinetic analyses, indicate a transfer between ECF and bone of as much as 500 mg of calcium daily, which is equivalent to one fourth to one half the total ECF calcium content. Besides regulating this transfer of calcium from bone through direct breakdown of bone tissue (mineral and matrix), PTH influences the rates of exchange of calcium adsorbed to the surface of bone; this exchangeable calcium pool can be stimulated to provide a rapid and substantial rate of entry of calcium into blood. In addition to these actions on bone, actions of PTH on the kidney may also be extremely important in the precise hourly regulation of ECF calcium. The third action of PTH on calcium homeostasis—namely, enhancement of intestinal calcium absorption—is indirect and involves the synthesis of $1,25(OH)_2D$ from the biologically inactive precursor 25(OH)D. However, it is difficult to quantitatively analyze or proportionately contrast the relative physiologic importance of the direct and indirect actions of PTH on the three principal target tissues: kidney, bone, and intestine.

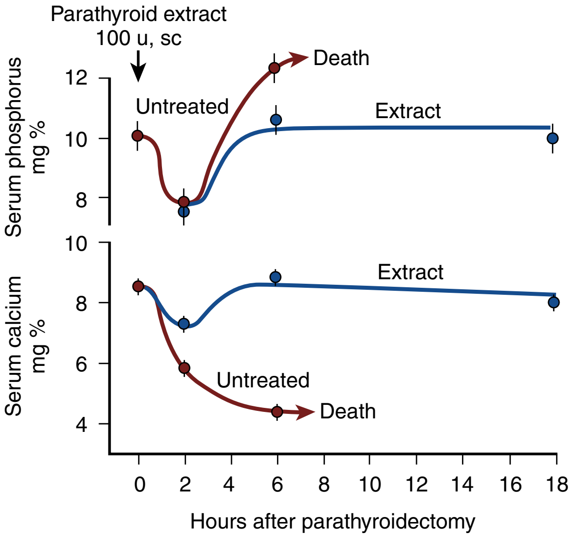

Fig. 47.1 **Biological actions of parathyroid hormone and calcium homeostasis.** Rate of change in blood phosphorus and calcium levels in rats with stressed calcium homeostasis (low-calcium diet) after parathyroidectomy without treatment or with parathyroid hormone extract given in addition at the time of parathyroidectomy. Rapid and usually fatal hypocalcemia and hyperphosphatemia result within hours unless hormone is given. *sc,* Subcutaneous. (Data from Munson PL. Studies on the role of the parathyroids in calcium and phosphorus metabolism. *Ann N Y Acad Sci.* 1955;60:776–796.)

The complexity of bone as a tissue and the many detectable rates of exchange of calcium between the skeleton and the ECF have made the action of PTH on the skeleton difficult to analyze. The physical state of calcium in blood is dynamic; much of the calcium is present as chelates or is bound to plasma proteins, but this bound or chelated form exchanges with the free ionized form of calcium that is also present in the blood at rates dependent on a variety of factors, such as the concentrations of counterions, such as phosphate (for detailed review see Chapter 52). Because actual filtered loads depend on the ratio of free and bound forms of calcium, it is difficult to calculate renal calcium clearance accurately. The different PTH-dependent actions to promote calcium entry into the ECF are most clearly defined in conditions of

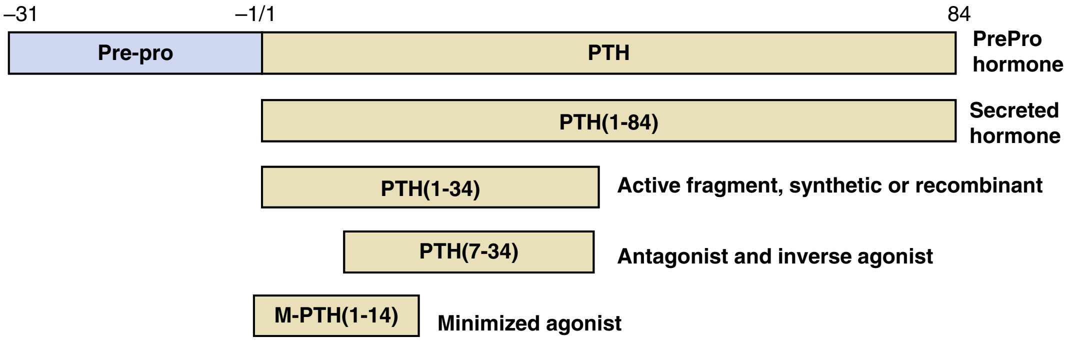

Fig. 47.2 **Parathyroid hormone (PTH) polypeptide and peptide derivatives.** Schematized are the biologically and pharmacologically relevant forms of the PTH polypeptide, including the nascent prepro PTH produced by parathyroid gland cells; mature PTH(1–84) that is secreted after removal of the prepro sequence; the PTH(1–34) fragment produced by chemical synthesis or recombinantly and which retains most if not all of the biological activity of intact PTH(1–84); the PTH(7–34) peptide that binds to but does not activate the PTH receptor type-1 and thus can function as a competitive antagonist, and, when modified with D-tryptophan at position 12, as an inverse agonist on constitutively active mutant PTH receptors, such as those found in patients with Jansen's metaphyseal chondrodysplasia,[88] and the N-terminal PTH(1–14) fragment that, when modified (M) with affinity-enhancing substitutions, functions *in vitro* as a potent agonist.

deficiency or excess of PTH, such as during experiments in animals or during controlled observations in patients with disorders of parathyroid gland function. The experimental data in these extremes abundantly affirm the crucial calcium homeostatic role of PTH. However, because of continuous and rapid adjustments in mineral ion concentration, it can be difficult to observe the consequences of hormone action under normal physiologic conditions. For example, the rate of PTH secretion changes continually and rapidly, so that the controlled variable, calcium, remains constant, and it may, therefore, be difficult to experimentally detect small corrective changes.

Teleologically, the action of PTH on the regulation of blood phosphate concentration in terrestrial species is best understood as a secondary, rather than a homeostatic, action. Phosphate is abundant in the food chain in terrestrial existence. Phosphate deficiency, unlike calcium deficiency, in the absence of specific organ dysfunction is, therefore, an unlikely environmental challenge (see Chapter 53 for detailed review of the regulation of phosphate homeostasis). To correct a deficiency in calcium, mineral stores in bone can be rapidly dissolved; such activity results, however, in the simultaneous liberation of ionic calcium and phosphate. Because a high blood phosphate level tends to lower the calcium concentration through multiple mechanisms, the rise in blood calcium that occurs after bone dissolution (desirable homeostatically) is, therefore, beneficial only if the concomitant increase in blood phosphate concentration (undesirable) can be rapidly corrected. To maximize the control of calcium homeostasis, PTH thus has divergent actions on renal tubular handling of the two mineral ions: it increases the retention of calcium and, at the same time, diminishes the reabsorption of phosphate. Through these mechanisms, namely, increased renal phosphate clearance to prevent hyperphosphatemia and increased tubular calcium reabsorption, PTH guarantees that an elevation in blood calcium results from the increased release of calcium from bone. The renal action of PTH on phosphate homeostasis is biologically predominant over the increased phosphate flux from bone. Consequently, parathyroidectomy or renal resistance to PTH, as in patients with pseudohypoparathyroidism or renal failure, can lead not only to severe or even fatal hypocalcemia, but also to an increase in blood phosphate and a marked reduction in urinary phosphate excretion (Fig. 47.1). This finding demonstrates the importance of the PTH-dependent action on phosphate homeostasis in the kidney, which becomes particularly important in disease states when high bone turnover is the result of dietary calcium deficiency or lack of biologically active vitamin D.

Parathyroid Hormone Chemistry

The first extracts from bovine parathyroid glands were described in the 1920s, and the content of biologically active PTH was assessed by their hypercalcemic and phosphaturic properties.[4,5] In the 1950s, extraction procedures were improved such that it became possible to purify sufficient quantities for biochemical analysis.[6] The amino acid sequences of the active purified PTH peptide from bovine, porcine, and human glands were obtained in the 1970s.[7,8] The sequences of the intact bovine, porcine, and human hormones each revealed a polypeptide chain of 84 amino acids (schematized in Fig. 47.2). Based on the derived amino acid sequences of the purified PTH(1–84) polypeptide, and clues derived from peptide fragmentation studies, the 1–34 fragments of PTH from several different species were chemically synthesized, and their biological activities *in vitro* and *in vivo* were found to be nearly equivalent to those of the corresponding intact hormone purified from the same species.[9] Molecular cloning techniques then led to the deduction of the amino acid sequences of PTH in several mammals[10] and subsequently in many other diverse species, including birds and fish, and more recently the identification of plausible PTH-like sequences in lower vertebrates and even invertebrates, as discussed in a later section of this chapter.

The potency of the PTH(1–34) fragment, observed both *in vitro* and *in vivo*, included its capacity to increase bone mass in animals. The latter findings led to the development of PTH(1–34) as a treatment for osteoporosis, and since 2001 the recombinant form of this peptide, teriparatide, has been in use as an effective therapy for that disease.[11] Extensive analysis of synthetic PTH peptides and a wide variety of derivative analogs (Fig. 47.2) in various types of pharmacological assays has led to the identification of the key structural elements in the molecule that determine its capacity to bind to the target PTH receptor and induce receptor activation responses that lead to downstream biologic effects. Truncated PTH fragment peptides, such as PTH(3–34), PTH(7–34), and PTH(15–34), established that the N- and C-terminal regions of PTH(1–34) contain the principal determinants of PTH receptor binding affinity and receptor activation potency, respectively. Analogs of the PTH(7–34) fragment thus function as competitive antagonists at the PTHR-1. Certain modified N-terminal peptides, such as the M-PTH(1–14) analog, have also been developed that contain affinity-enhancing modification and thus can adequately stimulate signaling responses in cells, further confirming the importance of the N-terminal region of PTH for receptor activation. Fig. 47.2 schematizes the various PTH analogs that help demonstrate the bipartite domain structure of the PTH(1–34) bioactive peptide. A more precise view of the mechanism by which PTH peptides interact with the PTH receptor has been made possible by the recent determination of the x-ray crystallography and cryogenic electron microscopy (cryo-EM) structures of the PTHR-1 obtained in complex with PTH(1–34) analog peptides, as discussed in a later section of this chapter.

KEY POINTS

- Parathyroid hormone (PTH) is an 84–amino acid polypeptide in which the first 34 amino acids comprise the biologically active region. Synthetic PTH(1–34) peptides are potent agonists at the PTH receptor type-1, a class B G protein–coupled receptor that mediates the key biological actions of PTH. PTH(7–34) peptides act as competitive antagonists.

Evolution of Parathyroid Hormone Ligands

Parathyroid glands, as discrete organs, first appeared in evolution with the amphibians, at the time of the migration of vertebrates from an aquatic to a terrestrial existence and the adaptation to an environment that is, by comparison to seawater, low in calcium. While fish lack parathyroid glands, immunologic and RNA hybridization studies provided evidence that PTH proteins are expressed in a variety of fish tissues, including the pituitary, brain, kidney, spinal cord, and developing jaw. Genomic studies have confirmed the presence of PTH coding sequences in a number of teleost fish, including the zebrafish (*Danio rerio*) and puffer fish (*Takifugu rubripes*).[12] The zebrafish genome contains six copies of *PTH*-like gene sequences, a number that presumably reflects a series of gene duplication events that occurred over the course of evolution of the vertebrate species.[13,14] Such gene duplication and gene loss models also explain the presence in humans and other higher vertebrates of genes encoding PTH, PTHrP, and a third homologous ligand called TIP39, which binds to the PTH-2 receptor subtype, as discussed in a later section of this chapter. Tracing the evolutionary path of the *PTH* and *PTHrP* gene-like sequences through diverse species can be confusing, given the occurrence of such genetic rearrangement events over time. Nevertheless, genome-based studies seem to provide ample support for the notion that PTH is an ancient hormone that was present in animals living at least as early as the time of the first appearance of the vertebrates, i.e., greater than approximately 500 million years ago. Indeed, gene sequences encoding putative peptides with at least weak or apparent similarity to vertebrate PTH ligands have even been identified in the genomes of several protochordates, including amphioxus (*Branchiostoma floridae*) and the sea squirt (*Ciona intestinalis*), as well as in the genomes of some insects.[13,15] These findings suggest that the ancestral *PTH*-like gene sequence emerged even prior to the divergence of the chordate lineages from the nonchordate metazoans.

Comparison of the amino acid sequences of PTH peptides from across species reveals a considerable amount of structural homology, particularly in the N-terminal portion of the hormone. Synthetic peptides corresponding to PTH-like sequences detected in the genomes of several lower vertebrates (e.g., zebrafish) as well as insects have been produced and shown to be active for inducing second-messenger (cAMP or intracellular calcium) signaling responses in experimental cells that heterologously express a target PTH receptor.[16] Such activities observed *in vitro* are at least consistent with a potential physiological role for the coded peptides in the parent organism, which also have been shown to contain genes for PTH-like receptors (discussed in a section that follows on the PTHR-1).[13,17] Analyses of messenger RNA or reporter gene expression levels in zebrafish indicate that at least some of the fish *PTH*-like genes are actively transcribed in certain tissues. The *PTH4* gene of zebrafish was thus found to be actively and exclusively expressed in the hypothalamus, both in early embryonic stages and in adults. This site of expression suggests an early neuroendocrine role for at least some PTH family ligands. Further functional analyses suggest that this role could involve a brain-to-bone signaling network that potentially ties in with mineral ion homeostasis, but such systems in lower vertebrates and invertebrates are not well understood.[12,14]

KEY POINTS

- Sequences encoding parathyroid hormone (PTH) or PTH-like peptides have been found in the genomes of several invertebrates, such as amphioxus (*Branchiostoma floridae*), indicating an early evolutionary origin.

The Parathyroid Hormone Gene and its mRNA

The human PTH gene consists of three exons located on chromosome 11p15.[10] The first exon is 85 bp in length and is noncoding. Exon 2 (90 bp) encodes most amino acids of the prepropeptide sequence. The third exon (612 bp) encodes the remainder of the propeptide sequence and all amino acids of the mature peptide. Exon 3 also contains the 3′ noncoding region. Two mRNAs that are 822 and 793 bp in length are derived from the human gene from the two transcriptional start sites that follow two different functional TATA boxes that are separated by 29 base pairs.[10] Genes encoding PTH ligands in the zebrafish exhibit at least some organizational similarity to mammalian PTH genes.[12,14]

KEY POINTS

- The parathyroid hormone gene in humans is located on chromosome 11p15 and is comprised of three exons, the first of which is noncoding, while exons 2 and 3 encode most of the prepro region and the remaining region to residue 84, respectively.

Parathyroid Hormone Biosynthesis and Intraglandular Processing

During the synthesis of the preproPTH molecule, the signal sequence, which comprises the 25–amino acid containing “pre” sequence, is cleaved off after entry of the nascent peptide chain into the intracisternal space bounded by the endoplasmic reticulum (ER). Heterozygous and homozygous missense mutations in this PTH leader sequence have been identified in patients with familial hypoparathyroidism.[18] Studies in cells indicate that such mutant polypeptide chains become trapped intracellularly, predominantly in the ER, leading to a marked upregulation of ER stress–responsive proteins (BiP and PERK) and the proapoptotic transcription factor CHOP. Such effects *in vivo* could likely give rise to apoptosis-mediated parathyroid cell death, thus explaining the observed hypoparathyroidism of the patients and the dominant nature of at least some of the mutations.

Subsequent to the removal of the presequence, the propeptide is transported to trans-Golgi network, where the prosequence (amino acid residues –6 through –1) is removed. This latter process may involve furin (paired basic amino acid cleaving enzyme) and/or proprotein convertase-7, which are both expressed in parathyroid tissue; their expression levels do not appear to be regulated by either calcium or $1,25(OH)_2D$. After removal of the basic prosequence, the mature polypeptide, PTH(1–84), is packaged into secretory granules. Two proteases, cathepsins B and H, are subsequently involved in the intraglandular generation of C-terminal PTH fragments from the intact hormone; no N-terminal PTH fragments appear to be released from the gland. Because small or intermediate size C-terminal fragments of PTH are unlikely to be involved in the regulation of calcium homeostasis, the intraglandular degradation of intact PTH is thought to represent an inactivating pathway, at least with regard to the regulation of mineral ion homeostasis. Consistent with this conclusion, hypercalcemia results in a substantial decrease in PTH secretion and, furthermore, favors the secretion of C-terminal PTH fragments (see later section on PTH metabolism). Several studies provide evidence that certain N-terminally truncated PTH fragments, such as PTH(7–84), can have hypocalcemic properties *in vivo*, and can furthermore reduce the formation of osteoclasts *in vitro*. While the underlying mechanisms for these observed effects remain to be established, it is at least conceivable that secreted C-terminal PTH fragments do contribute to the regulation of calcium homeostasis, at least under certain physiologic or pathophysiologic conditions.[19]

The pool of stored, intracellular PTH in parathyroid cells is small, and the cell must therefore have mechanisms to increase hormone synthesis and release in response to sustained hypocalcemia. One such adaptive mechanism is to reduce the intracellular degradation of the hormone, thereby increasing the net amount of intact, biologically active PTH that is available for secretion. During hypocalcemia the bulk of the hormone that is released from the parathyroid cell is intact PTH(1–84). As the level of $Ca^{2+}{}_o$ increases, a greater fraction of intracellular PTH is degraded, and with overt hypercalcemia most of the secreted immunoreactive PTH consists of biologically inactive C-terminal fragments.

KEY POINTS

- Parathyroid hormone is synthesized in cells of the parathyroid gland as a preprohormone, which is processed to the mature 1–84 peptide and stored in secretory vesicles until secretion is activated by low blood calcium levels.

Regulation of Parathyroid Hormone Gene Expression

Another adaptive mechanism of the parathyroid cell to sustained reductions in $Ca^{2+}{}_o$ is to increase cellular levels of PTH mRNA, a response that takes several hours. A reduction in $Ca^{2+}{}_o$ increases, whereas an elevation in $Ca^{2+}{}_o$ reduces, the cellular levels of PTH mRNA by affecting both its stability and the transcriptional rate of its gene. Phosphate ions also regulate, directly or indirectly, PTH gene expression. Hypophosphatemia and hyperphosphatemia in the rat lower and raise, respectively, the levels PTH mRNA through a mechanism that is independent of changes in $Ca^{2+}{}_o$ or $1,25(OH)_2D$. An elevated extracellular phosphate concentration could, thus, contribute importantly to the secondary hyperparathyroidism frequently encountered in patients with end-stage renal failure, who often have chronically elevated serum phosphate concentrations. FGF23, a major regulator of phosphate metabolism, has direct effects on the parathyroid gland to suppress the synthesis of PTH mRNA and protein.[1,3] In renal failure, in which high levels of both FGF23 and PTH are found, the parathyroid glands are resistant to the effects of FGF23 on PTH mRNA. This resistance is associated with decreased expression of FGF receptor 1 and α-Klotho, the receptor and coreceptor needed to transmit signals from FGF23, respectively, thereby explaining the paradox of increased levels of FGF23 and PTH in that condition.

Metabolites of vitamin D, principally $1,25(OH)_2D$, also play an important role in the long-term regulation of parathyroid function and may act at several levels: by suppressing the secretion of PTH and the transcription of its gene, by upregulating transcriptional activity of the genes encoding the calcium-sensing receptor (CaSR) (see later) and the vitamin D receptor (VDR), as well as by decreasing parathyroid cellular proliferation. $1,25(OH)_2D$ is by far the most important vitamin D metabolite that modulates parathyroid function. It acts through a nuclear receptor, the VDR, often in concert with other such receptors (i.e., those for retinoic acid or glucocorticoids), on DNA sequences upstream from the PTH gene (see Chapter 50). $1,25(OH)_2D$-induced upregulation of VDR and CaSR expression in the parathyroid could potentiate its inhibitory action(s) on PTH synthesis and secretion. Noncalcemic or less calcemic analogs of $1,25(OH)_2D$ inhibit PTH secretion while producing relatively little stimulation of intestinal calcium absorption and bone resorption, and may thus be attractive candidates for treating the hyperparathyroidism of chronic renal insufficiency.

Adjustment of the rate of parathyroid cellular proliferation is the third adaptive mechanism contributing to changes in the overall secretory activity of the parathyroid gland. Under normal conditions, parathyroid cells have little or no proliferative activity. The parathyroid glands, however, can enlarge greatly during states of chronic hypocalcemia, particularly in the setting of renal failure, probably because of a combination of hypocalcemia, hyperphosphatemia, and low levels of $1,25(OH)_2D$ in the latter condition.

Regulation of Parathyroid Hormone Secretion

The most important physiological factors that regulate PTH secretion are the concentrations of $Ca^{2+}{}_o$, $1,25(OH)_2D$, and extracellular phosphate ions. Of these three, $Ca^{2+}{}_o$ is most important in the minute-to-minute control of PTH secretion. Indeed, the actions of $1,25(OH)_2D$ and phosphate ions on the secretion concentrations of PTH probably result, at least in part, from their effects on hormonal biosynthesis rather than secretion *per se*. $Ca^{2+}{}_o$ also modulates several other aspects of parathyroid function that indirectly affect PTH secretion, including PTH gene expression, the hormone's intracellular degradation, and parathyroid cellular proliferation, as described previously. FGF23 and α-Klotho (a coreceptor for FGF receptors), also modulate parathyroid function, by inhibiting both PTH secretion and *PTH* gene expression. FGF23 also has important actions on $Ca^{2+}{}_o$ homeostasis, through inhibition of the formation of $1,25(OH)_2D$.

Physiologic Control of Parathyroid Hormone Secretion by Extracellular Calcium Ion

As illustrated in Fig. 47.3A, the relationship between PTH and $Ca^{2+}{}_o$ is represented by a steep inverse sigmoidal curve that can be quantitatively described by four parameters.[20] These are the maximal rate of PTH secretion at low $Ca^{2+}{}_o$ (parameter A); the slope of the curve at its midpoint (parameter B); the value of $Ca^{2+}{}_o$ at the midpoint (e.g., the "set point" or the level of $Ca^{2+}{}_o$ half-maximally suppressing PTH release; parameter C); and the minimal secretory rate at high $Ca^{2+}{}_o$ (parameter D). Parameter A *in vivo* is the sum of the maximal rates of PTH release from all individual parathyroid chief cells, as reflected by the resultant, maximally stimulated level of circulating PTH. Because of the steepness of the $Ca^{2+}{}_o$–PTH relationship, small alterations in $Ca^{2+}{}_o$ evoke large changes in PTH release, thereby contributing importantly to the near constancy of $Ca^{2+}{}_o$ *in vivo*. Indeed, parathyroid cells can readily detect and correct reductions in $Ca^{2+}{}_o$ of a few percentage points, leading to a percent coefficient of variation in $Ca^{2+}{}_o$ in humans that is less than 2%. The set point of the parathyroid gland is the key determinant of the level at which Ca^{2+}o is "set" *in vivo*, although the parathyroid set point is usually slightly lower than the ambient blood calcium concentration. Thus, the parathyroid cell is normally more than half-maximally suppressed at normal levels of Ca^{2+}o and has a large secretory reserve for responding to hypocalcemic stress. Nevertheless, PTH levels in vivo also fall dramatically (e.g., by 80%) when Ca^{2+}o rises to frankly hypercalcemic levels, which is thought to contribute importantly to the mineral ion homeostatic system's defense against hypercalcemia.[21] Evidence, however, from studies using mice with knockout of PTH or both PTH and the extracellular CaSR have shown that, even in the total absence of PTH, the high calcium-evoked increases in renal calcium excretion and calcitonin secretion provide a robust defense against hypercalcemia.[22]

Elevating Ca$^{2+}_{o}$ also decreases the proportion of secreted, intact PTH because of increased intraglandular degradation to inactive fragments (see the earlier section entitled Parathyroid Hormone Biosynthesis and Intraglandular Processing and the later section entitled Metabolism of Parathyroid Hormone). Even with severe hypercalcemia, however, some residual release of intact PTH(1–84) still occurs *in vivo* and persists at a level approximately 5% of that observed with a maximal hypocalcemic stimulus (see Fig. 47.3). This nonsuppressible basal component of PTH release may contribute to the hypercalcemia caused by hyperparathyroidism when the mass of abnormal parathyroid tissue is very great (e.g., in patients with renal failure).[20]

The parathyroid cell has a temporal hierarchy of responses to low Ca$^{2+}_{o}$ that permits it to secrete progressively larger amounts of hormone during prolonged hypocalcemia. To meet acute hypocalcemic challenges, PTH is released within seconds from preformed secretory vesicles by exocytosis as dictated by the sigmoidal curve (see Fig. 47.3). Sufficient PTH is stored in the parathyroid chief cell to sustain maximal, low Ca$^{2+}_{o}$-stimulated PTH release for approximately 60 to 90 minutes. Another rapid response of the parathyroid cell to hypocalcemia that enhances its net synthetic rate of PTH is reduced intracellular hormonal degradation—the opposite of what occurs at high levels of Ca$^{2+}_{o}$—which occurs within minutes to an hour. Hypocalcemia persisting for hours to days elicits increased PTH gene expression, whereas that lasting for days to weeks or longer stimulates parathyroid cellular proliferation. A greater secretory capacity for PTH on a per-cell basis (e.g., as a result of enhanced PTH gene expression) increases maximal hormonal secretion *in vivo*, as does an increase in cell number as a result of parathyroid cellular proliferation. In severe secondary hyperparathyroidism, very large increases in parathyroid cellular mass can elevate circulating PTH levels by 100-fold or more.

In addition to responding to changes in Ca$^{2+}_{o}$ *per se*, the parathyroid cell also appears to sense the rate of change in Ca$^{2+}_{o}$ such that rapid decrements in calcium promote more vigorous secretory responses than do changes of a similar magnitude occurring more slowly. Furthermore, during dynamic testing of parathyroid function *in vivo* by induced increases or decreases in Ca$^{2+}_{o}$, PTH in blood is higher at a given serum calcium concentration when Ca$^{2+}_{o}$ is falling than when it is rising (e.g., there is hysteresis in this relationship). The latter results in an apparent direction dependence of the secretory response, which, when combined with the rate dependence just described, may allow for a physiologically appropriate, more vigorous secretory response to large rapid decrements in Ca$^{2+}_{o}$. Also present are circadian and more rapid (i.e., occurring at rates of one to six pulses per hour) phasic changes in circulating PTH levels, but the physiologic significance of these changes is not known.

KEY POINTS

- The processes of parathyroid hormone (PTH) synthesis and secretion in parathyroid gland cells are tightly regulated by the calcium-sensing receptor (CaSR), a class C G protein–coupled receptor. The CaSR binds calcium cooperatively such that small changes in blood calcium levels lead to significant changes in blood PTH levels.

Mechanism of Extracellular Calcium Ion Sensing by Parathyroid Cells and Other Cells Involved in Mineral Ion Homeostasis

The molecular mechanism underlying Ca$^{2+}_{o}$-regulated PTH secretion involves the CaSR expressed on the surface of cells in the parathyroid glands.[22,23] The CaSR is a member of the class C subgroup of the GPCR protein superfamily.[24] Depending on cell type and experimental conditions, the CaSR can couple to several G protein signaling mediators, including $G_{q/11}$, G_i, $G_{12/13}$, and G_s, which, in turn, lead to the stimulation of phospholipase C (PLC), the inhibition of adenylate cyclase, the activation of Rho kinase, and the activation of adenylate cyclase, respectively. Patient-based studies described below indicate that G_{11} plays a particularly dominant role in mediating the control of PTH secretion via the CaSR.

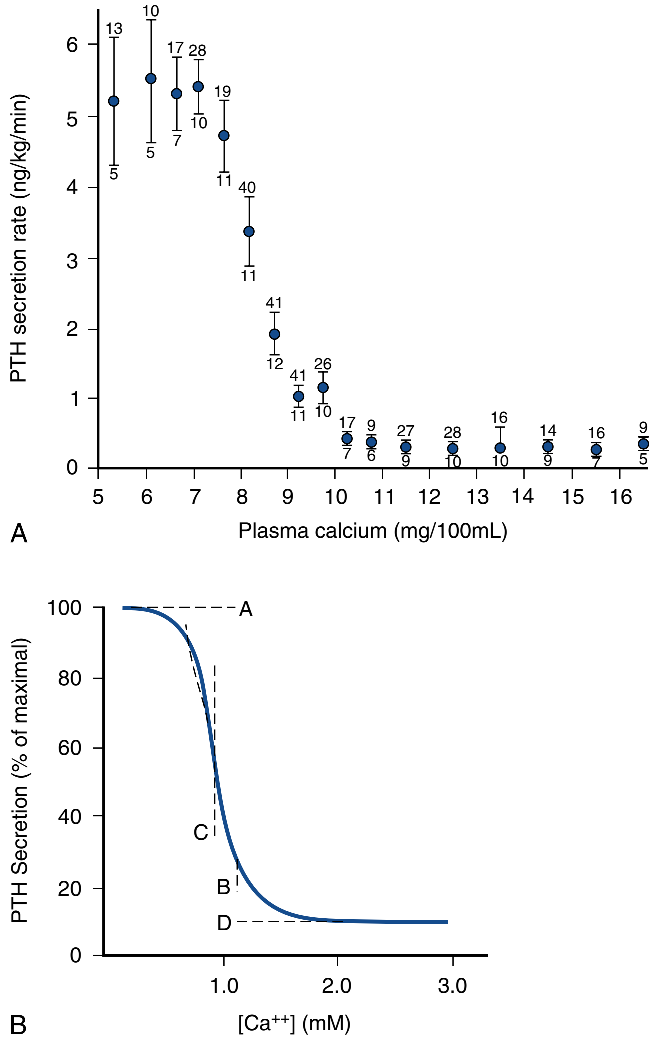

Fig. 47.3 Inverse sigmoidal relationship between calcium (Ca++) and parathyroid hormone (PTH) release and the four-parameter model describing these curves. A, Secretory response of bovine parathyroid glands to induced alterations in plasma calcium concentration. Calves were infused with calcium or ethylenediaminetetraacetic acid, and PTH secretion was assessed by measuring PTH levels in the parathyroid venous effluent. The symbols and vertical bars indicate the secretory rate (mean ± standard error) in calcium concentration ranges of 1.0 or 0.5 mg/100 mL. The number of calves and samples are indicated by numbers below and above, respectively. **B,** Sigmoidal curve generated by the equation Y = [(A − D)/(1 + (X/CB)] + D; the significance of A, B, C, and D are described in the text. (**A** from Mayer GP and Hurst JG. Sigmoidal relationship between parathyroid hormone secretion rate and plasma calcium concentration in calves. *Endocrinology*. 1978;102(4):1036–1042.)

The protein topology of the CaSR, as for other class C GPCRs, is characterized by a large N-terminal extracellular domain (ECD) that contains a bilobed, Venus flytrap (VFT)-like structure (Fig. 47.4). The

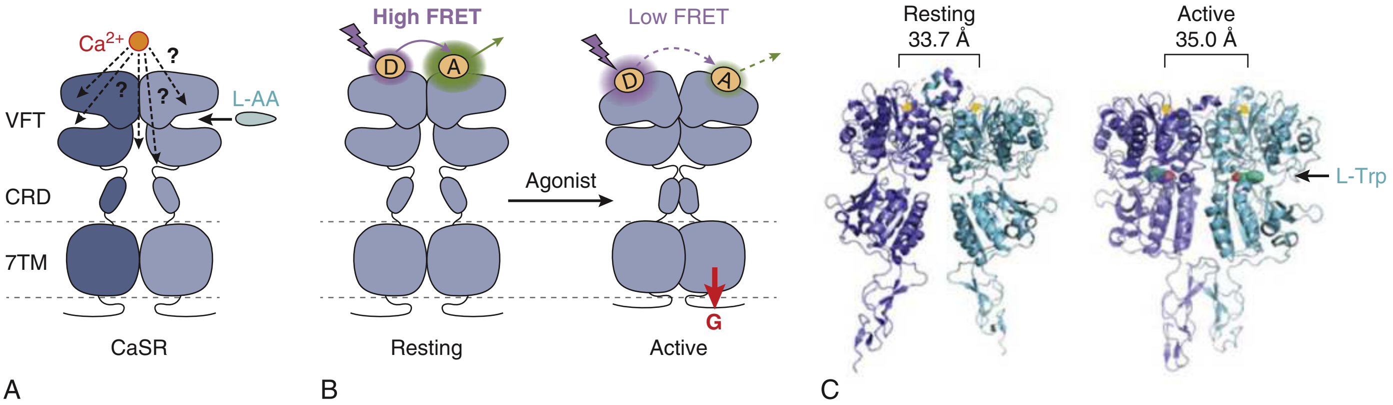

Fig. 47.4 **Calcium-sensing receptor (CaSR) structure and models of activation. A,** Schematic showing the dimeric organization of the CaSR; each receptor monomer contains a large extracellular domain (ECD) that is seen in x-ray crystallography structures.[25,26] The ECD is comprised of a two-lobed venus fly trap (VFT) domain and a cysteine-rich domain (CRD), which joins to the seven-helix bundle of the transmembrane domain (7TM). A binding site for an L-amino acid (L-AA) lies between the two lobes of each VFT. The location of binding sites for calcium (Ca^{2+}) remain uncertain, but mutational and Förster resonance energy transfer (FRET)-based studies are consistent with two functionally important Ca^{2+} binding sites in each VFT monomer. **B,** FRET-based studies using CaSR monomers tagged with fluorescent donor (D) and acceptor (A) probes support a closing of the VFTs upon binding agonist (e.g., Ca^{2+}), which leads to receptor activation and G protein coupling, a process potentiated by binding of an LAA.[27] **C,** Crystal structure–based models of the CaSR ECD in the inactive, open state obtained in the presence of low calcium (*left*, protein database [PDB] file 5K5T) and in the active, closed state obtained in the presence of high calcium (*right*, PDB 5K5S). Residue Asp23, tagged in each monomer with fluorescent FRET probes used to assess interlobe distances, measured as ångstrom (A˚), is shown as yellow spheres. (Reproduced with permission from Liu H, Yi P, Zhao W, et al. Illuminating the allosteric modulation of the calcium-sensing receptor. *Proc Natl Acad Sci U S A*. 2020;117(35):21711–21722.)

structure of the CaSR ECD has been determined by x-ray crystallography, and is thus seen to form a homodimer that is linked by a disulfide bond between cysteine residues located at position 129 at the top of each VFT domain.[25,26] A cysteine-rich domain links the VFT of each monomer to the corresponding heptahelical transmembrane domain (TMD) portion of the receptor, which mediates G protein coupling. The VFT of the CaSR plays a critical role in the receptor's capacity to bind extracellular calcium and likely other stimuli.[27] The x-ray crystallographic structures were obtained both in the absence and presence of high levels of calcium, and differences observed in the two structures provide clues about the mechanism of calcium-induced activation of the CaSR. In the calcium-free state, the two lobes of the VFT, which appear to be connected by a hinge, are open to form a cleft between the two lobes. In the calcium-bound state, the two lobes are closed together. It can thus be inferred that calcium binding leads to a shift of the VFT from an open, resting state to a closed, active-state conformation, and this closing, in turn, leads to a change in the TMD portion of the receptor and G protein activation (see Fig. 47.4).[27,28] Several bound calcium[26] or magnesium[25] atoms were observed in the ECD structures, although the bound divalent metal ions were not located at two sites that are predicted by modeling and mutational data to be particularly critical for calcium binding and function.[27] The structures also revealed an aromatic amino acid, L-tryptophan or a derivative, bound in the cleft between the two lobes of the VFT, and functional studies support a critical role in activation for binding of such an aromatic acid (see later). Intriguingly, the CaSR ECD structures also revealed several bound phosphate groups,[26] which has opened the possibility that this ion can act to negatively regulate CaSR function, as also discussed following.

The CaSR manifests marked positive cooperativity in its activation by $Ca^{2+}{}_o$, probably as a result of having at least two binding sites for $Ca^{2+}{}_o$ in each lobe of the VFT, as well as a binding site for an aromatic amino acid.[25-27] At least one key $Ca^{2+}{}_o$-binding site is thought to be located in the crevice between the two lobes of the VFT and adjacent to the amino acid binding site. Dynamic Förster resonance energy transfer–based studies of fluorescently labeled CaSR constructs show that such aromatic acids act as positive allosteric modulators (PAMs) for the CaSR and promote activation induced by calcium ions.[27] In contrast to L-amino acids, which bind to the VFT, small-molecule ligands, such as NPS R568, that also act as PAMs for the CaS, appear to bind to the TMD region of the receptor, suggesting that these compounds promote CaSR activation via a distinct mechanism.[29] Compounds that act as negative allosteric modulators for the CaSR have also been identified, but their binding sites have not been well characterized.[30] The full sequence of events by which the binding of calcium and other ligands to the CaSR alters the configuration of the receptor and its coupling to downstream signaling effectors remains to be established, as structures of the intact receptor have not yet been reported. Moreover, the potential role of phosphate in acting as a negative feedback modulator of CaSR signaling, as suggested by *ex vivo* functional studies,[31] also remains to be established.

The identification of hypercalcemic (e.g., familial hypocalciuric hypercalcemia [FHH] and neonatal severe hyperparathyroidism) and hypocalcemic (i.e., autosomal dominant hypocalcemia) disorders caused by inactivating and activating mutations of the CaSR, respectively, has provided incontrovertible proof of the receptor's central, nonredundant role in setting the serum calcium concentration.[22,28] Patients with these disorders have characteristic abnormalities in parathyroid and renal calcium sensing/handling. Heterozygous inactivating mutations of $G\alpha_{11}$ have been identified in patients with a form of FHH called FHH type 2, while activating mutations of $G\alpha_{11}$ have been shown to be the cause of autosomal dominant hypoparathyroidism type 2.[32,33] The $G\alpha_{11}$ protein, therefore, seems to be a key downstream effector of the CaSR in regulating PTH secretion, presumably by stimulating

PLC and modulating levels of intracellular calcium and other signaling molecules. Other second messenger pathways that might be involved as mediators of Ca^{2+}_o-induced suppression of PTH secretion remains uncertain, but these could potentially include arachidonic acid production by PLA_2, stimulation of ERK1/2, and elevation of cAMP.

The CaSR is also expressed in several additional tissues involved in systemic mineral ion homeostasis, including the calcitonin-secreting C-cells of the thyroid, diverse cells within the kidney, bone cells and/or their precursors, and intestinal epithelial cells. In the C-cell, the CaSR mediates the stimulatory action of high Ca^{2+}_o on calcitonin secretion, a Ca^{2+}_o-lowering hormone with unclear physiological significance in humans. In the kidney, the CaSR in the cortical thick ascending limb of the nephron mediates direct high Ca^{2+}_o–induced inhibition of the tubular reabsorption of calcium and magnesium. Therefore, raising Ca^{2+}_o directly inhibits renal tubular reabsorption of calcium via actions on the CaSR expressed in nephron segments involved in hormonal regulation of calcium reabsorption (e.g., by PTH) and indirectly inhibits it by reducing PTH secretion (see the later section Renal Calcium Reabsorption). The CaSR is expressed by chondrocytes as well as by osteoblasts and osteoclasts and/or their precursors, and some data suggest that it plays key roles in skeletal development, as well as bone anabolism.[34,35] It is not currently known whether the CaSR expressed in intestinal epithelial cells plays any role in regulating $1,25(OH)_2$ D-mediated absorption of calcium.

KEY POINTS

- The calcium-sensing receptor (CaSR) extracellular domain is characterized by a venus fly trap domain that contains binding sites for calcium as well as other ligands, including phosphate and an aromatic L-amino acid. The CaSR functions as a homodimer and couples to the Gα11 signaling cascade.

$1,25(OH)_2D$, Phosphate, and Other Factors Regulating Parathyroid Hormone Secretion

In addition to directly inhibiting *PTH* gene expression, $1,25(OH)_2D$ also reduces PTH secretion. It is not known whether this latter action is solely secondary to the effect of $1,25(OH)_2D$ on biosynthesis of the hormone and/or represents a direct action on the secretory process *per se*. Increasing the ambient level of phosphate *in vitro*, independent of concomitant changes in Ca^{2+}_o, enhances parathyroid cellular proliferation, *PTH* gene expression, and hormonal secretion. Phosphate-induced changes in PTH secretion, however, take several hours and may result secondarily from changes in hormonal biosynthesis rather than secretion *per se*. Finally, extracellular magnesium ion (Mg^{2+}_o) clearly functions as a CaSR agonist *in vitro*, although it is 2-fold to 3-fold less potent than Ca^{2+}_o.[27] Because levels of serum ionized Mg^{2+}_o are lower than those of Ca^{2+}_o, it is presently unclear whether Mg^{2+}_o acts as a physiologically relevant CaSR agonist at the parathyroid gland *in vivo* under normal circumstances. Patients with inactivating or activating CaSR mutations, however, can exhibit mild hypermagnesemia or hypomagnesemia, respectively, suggesting that the CaSR does contribute to setting Mg^{2+}_o *in vivo*.

KEY POINTS

- Parathyroid hormone acts in concert with $1,25(OH)_2D$ and FGF23 as part of a tightly integrated signaling network that operates to maintain blood levels of calcium as well as phosphorus.

Metabolism of Parathyroid Hormone

In addition to the full-length polypeptide PTH(1–84), which is the biologically active hormone, circulating PTH fragments that lack an intact N-terminus can generally be readily detected, and most of these fragments are devoid of biologic activity, at least with regard to the PTHR-1.[36] C-terminal PTH fragments are produced in and released from the parathyroid gland, but they are also derived from the circulating intact hormone by degradative systems active in the liver, kidney, and other peripheral sites. However, some PTH fragments, such as PTH(7–84), appear to be generated within the gland and may have some biological activity. The relative concentration of such C-terminal fragments released from the gland increases under conditions of systemic hypercalcemia, when overall secretion rates of intact hormone are lower. The secreted C-terminal PTH fragments are similar to those generated by peripheral metabolism (see later) but have not been chemically characterized. Studies in animals show that the clearance of intact PTH from plasma is very rapid (half-life: 2–4 min), and the liver and kidney are the major organ sites of PTH clearance. Hepatic mechanisms are estimated to account for 40% to 75% of intact hormone clearance, while renal mechanisms account for approximately 20% to 30% of total peptide clearance.

The current evidence therefore indicates that intact PTH and multiple C-terminal fragments (which are derived from glandular and peripheral cleavage and may not be identical) are the principal circulating hormonal forms. Biologically active, N-terminal fragments of PTH, if found in the circulation at all, are likely to circulate only at extremely low concentrations ($<10^{-13}$ to 10^{-14} mol/L).[36] Several different immunometric assays have been developed for detecting PTH in the circulation. These assays each use two different antibodies: an immobilized capturing antibody directed against the C-terminal portion of PTH(1–84) and an enzyme-labeled detection antibody directed against the N-terminal portion of the intact molecule. The precise epitopes may differ for the different antibodies used in the various assays used clinically, which can lead to ambiguity in the results obtained for patient samples analyzed with two or more of the assays.[37] Nevertheless, the different assays have been helped in demonstrating the presence of different forms of PTH fragments.

The careful immunometric analysis of circulating PTH levels has considerable significance for the management of patients with parathyroid dysfunction, especially in the presence of renal failure. Particularly during hypercalcemia, N-terminally truncated forms of PTH become a significant, if not the dominant, PTH species. Measurements of "intact" PTH by earlier assays had, therefore, overestimated the concentrations of biologically active PTH, and so could result in the overtreatment of uremic patients with vitamin D analogs and/or calcium. The resulting suppression of the parathyroid gland, even without evoking an inhibitory effect of a fragment similar to PTH(7–84), could be acting together to excessively reduce PTH-dependent bone turnover. When secretion of PTH is suppressed, as in hypercalcemia, and the fractional concentration of the large, N-truncated PTH increases, however, inhibition of the actions of native PTH on calcium or bone could occur. Experiments with synthetic PTH(7–84) support the conclusion that such actions occur *in vivo* and *in vitro*. For example, PTH(7–84) was shown to have hypocalcemic properties *in vivo*, and it reduces, potentially via an as yet unidentified receptor specific for the C-terminal portion of PTH, bone resorption that may be partly due to impaired osteoclast differentiation. Newer immunoassays that do not detect such amino terminally truncated PTH molecules likely offer a decisive advantage in diagnosis and management of secondary hyperparathyroidism (see Chapters 54 and 56).

KEY POINTS

- Parathyroid hormone (PTH) 1–84 exhibits a short half-life in the circulation of approximately 2–4 minutes, due in large part to cleavage and clearance mechanisms operating in the liver and kidney. C-terminal fragments such as PTH(7–84) can be detected as circulating metabolites, particularly in patients with renal insufficiency.

PARATHYROID HORMONE–DEPENDENT REGULATION OF MINERAL ION HOMEOSTASIS MEDIATED THROUGH THE PARATHYROID HORMONE RECEPTOR TYPE-1

PTH is, as outlined earlier, the most important peptide regulator of mineral ion homeostasis in mammals. Through its actions on the kidney and bone, PTH maintains blood calcium concentration within narrow limits. In bone it stimulates the release of calcium, while in the kidney, it enhances renal tubular reabsorption of calcium (and diminishes tubular reabsorption of phosphate). Furthermore, in the kidney it stimulates the synthesis of renal 1α-hydroxylase, which leads to an increase in the renal production of 1,25(OH)$_2$D, that, in turn, promotes the intestinal absorption of calcium (and phosphate). These direct and indirect endocrine actions of PTH are mediated through PTHR-1, a class B GPCR that is abundantly expressed in both major target tissues of PTH action, bone and kidney.

Actions of Parathyroid Hormone on the Kidney

In addition to regulating renal calcium and phosphate transport, PTH modifies the tubular handling of magnesium, sodium, potassium, bicarbonate, and water, and moreover stimulates renal gluconeogenesis. Specific regions of the nephron that are involved in each of the PTH-dependent actions have been defined through *in vivo* micropuncture analyses and through *in vitro* studies with nephron segments that have been dissected from the remainder of the kidney. Furthermore, cell lines from specific regions of the kidney have also been used. However, interpretation of these results has to take into account the complexity of the organization of the kidney as an organ (for example, the complex anatomic relationship involving different renal tubular segments spanning both the cortex and medulla and the effects of countercurrent distribution that modify solute and water transport), particularly because certain *in vivo* features of renal tubules are not readily imitated *in vitro* through the use of isolated tubules or cells.

Renal Calcium Reabsorption

Most of the calcium in the glomerular filtrate is reabsorbed. The bulk of this reabsorption (65%) occurs via passive, paracellular mechanisms, both in the proximal tubules and, to a lesser extent, in the thick ascending limb of Henle's loop and the distal convoluted tubule. The CaSR also plays an important, PTH-independent role in the adjustment of renal calcium reabsorption in the cortical thick ascending limb. The physiologically important stimulation of renal calcium reabsorption by PTH occurs almost entirely in the distal nephron. In the cortical thick ascending limb (TAL), PTH increases the magnitude of the positive charge potential of the lumen that drives the passive, paracellular reabsorption of calcium and magnesium. In the distal convoluted tubule, in contrast, PTH promotes increased transcellular calcium reabsorption by coordinate upregulation of molecular components of this transcellular pathway. PTH enhances uptake of calcium into the distal tubular cells via the (luminal) plasma membrane channel, TRPV5, as well as its active extrusion into the blood against a steep electrochemical gradient at the basolateral membrane. This latter process of extrusion involves two types of transporters. One is the plasma membrane calcium pump (Ca^{2+}/Mg^{2+}-ATPase, PMCA), and the second is a Na^+/Ca^{2+} exchanger (NCX1), which, in turn, is indirectly regulated by Na^+/K^+-ATPase(s), which maintains the transcellular sodium gradient. Studies performed with membrane vesicles from the distal region of the kidney show increased activity of the Na^+/Ca^{2+} exchanger in response to PTH. PTH also stimulates the translocation of preformed calcium channels sequestered within the interior of certain distal tubular cells, presumably TRPV5, to the apical (i.e., luminal) surface of the renal tubular epithelial cell and mediate increased cellular calcium uptake. Because PTH simultaneously enhances the activity of Na^+/Ca^{2+} exchangers in the basolateral (antiluminal) membrane, the overall process promotes an increase in transcellular calcium uptake from the lumen to blood, that is, from the apical to the basolateral membrane.

More recent studies in mice reveal that PTHR-1 signaling in the TAL downregulates claudin-14, a tight junction factor that inhibits paracellular calcium transport in the TAL.[38] Additionally, the membrane abundance of TRPV5 in cells of the TAL has been shown to be negatively regulated by phosphorylated claudin-16, mutations in which cause hypomagnesemia with hypercalciuria and nephrocalcinosis, and PTHR-1 signaling promotes claudin-16 phosphorylation, which would thus augment calcium reabsorption via TRPV5.[39]

Regulation of 1α- and 24-Hydroxylase Activity

PTH is a major inducer of the activity of proximal tubular 1α-hydroxylase, a microsomal cytochrome P-450 enzyme that synthesizes biologically active 1,25(OH)$_2$D from the substrate 25(OH)D. This effect of PTH on synthesis of the renal enzyme shows longer lag times than its effect on renal calcium transport and is mediated, at least in part, by the protein kinase A (PKA) signaling pathway of the PTHR-1. Although 1α-hydroxylase activity has been detected in several nonrenal tissues, its mRNA is found in abundant concentrations only in the kidney, confirming that this organ is the most important site for the generation of 1,25(OH)$_2$D. PTH-dependent synthesis of new 1α-hydroxylase protein, which only occurs in the renal proximal tubule, requires several hours and is blocked by 1,25(OH)$_2$D. Studies in mice have revealed a renal-specific transcriptional control element located distal to the *Cyp27b1* gene, which encodes the 1α-hydroxylase and is required for responsiveness to regulation by PTH, as well as FGF23.[40] The element appears to be involved in a longer-range control of *Cyp27b1* promoter activity, likely via effects on chromatin structure in that genetic locus. Hypophosphatemia is, similar to PTH, a major inducer of 1α-hydroxylase, though it is still unclear whether the effects of hypophosphatemia are independent of effects on FGF23 levels in the blood. In contrast, hypercalcemia, as would be generated by sustained increases in circulating levels of PTH or PTHrP, suppresses synthesis of the enzyme, thus limiting overall 1,25(OH)$_2$D synthesis in a homeostatic manner. The molecules 25(OH)D and 1,25(OH)$_2$D can also be hydroxylated by the 24-hydroxylase, resulting in the inactive metabolites, 24,25(OH)$_2$D and 1,24,25(OH)$_3$D (see Chapter 50). PTH has an inhibitory effect on the 24-hydroxylase, thus reducing the inactivation of 1,25(OH)$_2$D; in contrast, 1,25(OH)$_2$D stimulates the synthesis of 24-hydroxylase, thereby inducing its own metabolism.

Renal Phosphate Transport

PTH is of major importance for maintaining normal blood calcium levels, but it is not the principal regulator of the serum phosphate concentration, which appears to depend on specific phosphaturic factors, particularly FGF23 (see Chapter 53). However, when PTH causes an increase in bone resorption (as might occur with prolonged dietary calcium deprivation), calcium and phosphate increase simultaneously in the blood. Although calcium is needed, phosphate is best excreted, which is mainly accomplished by a PTH-stimulated increase in renal phosphate clearance.

PTH acts directly on proximal tubular cells, where it regulates the expression of the type II sodium-phosphate cotransporters, NPT2a and NPT2c, and the abundance of these protein in the apical brush border membrane (BBM). PTH thus induces phosphaturia by increasing the internalization of NPT2a and NPT2c, and hence reducing their functional expression at the apical, BBM surface of the proximal tubule cells. Both the cAMP/PKA- and intracellular calcium/IP_3/protein kinase C (PKC)-dependent signaling pathways appear to contribute to the PTH-induced reduction in proximal tubular phosphate reabsorption.[41,42] Evidence supporting a predominant role for the cAMP/PKA pathway, however, in the PTH-dependent regulation of renal phosphate transporters comes from patients with pseudohypoparathyroidism type Ia. This disease is caused by maternally inherited, inactivating mutations in *GNAS*, i.e., the gene encoding the stimulatory G protein Gsα.[43] Patients develop hyperphosphatemia due to a lack of functional Gsα in the proximal tubules, and consequently show impaired urinary cAMP and phosphate excretion in response to PTH (see Chapters 53 and 57).

NPT2a and NPT2c appear to have distinct roles in regulating phosphate transport in the kidney. NPT2a is expressed in segments S1 through S3 of the proximal tubule, whereas NPT2c is expressed only in the S1 segment. NPT2a protein undergoes lysosomal degradation upon internalization in response to PTH, whereas NPT2c appears to be recycled and reinserted into the BBM after initial internalization. The mechanisms underlying these diverse response profiles are uncertain at present. In mice, the mRNA encoding NTP2c is approximately 10-fold less abundant than that encoding NPT2a, suggesting that NTP2c plays only a minor biological role in mice, limited to some period during postnatal development. However, in humans, homozygous and compound heterozygous mutations in NPT2c are known to cause hereditary hypophosphatemic rickets with hypercalciuria, an autosomal recessive disorder. This disease linkage makes it certain that NPT2c serves important functions in biology and is not redundant with NPT2a. Homozygous, inactivating mutations in NPT2a are the cause of a more severe disease leading not only to renal phosphate wasting, but also to the impairment of other proximal tubular functions and severe hypercalcemia.

Intracellular scaffold proteins, in particular the NHERF family of proteins, play important roles in the PTH-mediated regulation of NPT2a and NPT2c expression at the cell surface.[42,44,45] NHERF-1-null mice display phosphate wasting due to a reduction in NPT2a expression at the BBM of proximal tubules. NHERF-1 interacts with the PTHR-1, as well as NPT2a, via PDZ domain–based scaffolding interactions that involve PDZ domain recognition motifs located on the C-terminal tail of the PTHR-1 and on cytoplasmic segments of the transporter proteins. PTHR-1 signaling induces phosphorylation of Ser290 in NHERF-1 as a key step in the mechanism by which PTH regulates NPT2a-mediated phosphate uptake, presumably in part by promoting dissociation of NPT2a–NHERF-1 complexes at the BBM membrane.[42,44] Other studies have shown that PTHR-1 coupling to NHERF proteins can lead to changes in the specific signaling pathways activated by the receptor, at least in certain cells. NPT2a expression in the renal BBM and its interaction with NHERF proteins can further be regulated by FGF23, as well as by $1,25(OH)_2D$, as shown by studies in the Hyp mouse model of human X-linked hypophosphatemia.[45]

KEY POINTS

- Parathyroid hormone (PTH) stimulates calcium reabsorption in the distal nephron through effects on both passive paracellular transport and active transcellular processes, the latter involving TRPV5 calcium channels. In proximal tubule cells, PTH stimulates the synthesis of the 1α-hydroxylase, and hence the formation of $1,25(OH)_2D$, as well as the downregulation of NPT2a and NPT2c, and hence the urinary excretion of phosphorus.

Actions of Parathyroid Hormone on Bone

PTH actions on bone cells are critical in the normal process of bone development and maintenance of skeletal integrity in the adult, as well as playing a crucial role in calcium and phosphate homeostasis through its actions on target cells. In bone, PTH affects several highly specialized cells, i.e., osteoblasts, osteocytes, and osteoclasts, that are critical in bone health and integrity and, as discussed later, are used in generating some of the homeostatic responses in mineral ion metabolism. The actions of PTH on cells of the osteoblast lineage reflect direct actions of PTH, while the effects on osteoclasts are indirect, mediated in an autocrine/paracrine manner through factors released by osteoblasts and osteocytes in response to PTH receptor activation. PTH actions on bone cells are critically influenced by the actions of vitamin D (see Chapters 50 and 51) and closely intertwined with the actions of PTHrP (see Chapter 48). PTH actions on bone are but one factor in a complex pattern of interactions involving multiple systemic and locally produced hormones and cytokines, for example, sex steroids.

The tools of mouse genetics have permitted remarkable advances in unraveling the complex pattern of interactions due to PTH by selective gene knockout of individual components of the interacting system, followed by observation of the effects *in vivo*. Mouse models in which PTH action has been selectively blocked exhibit a marked reduction in trabecular bone, indicating a role for PTH in bone development and a close interplay between PTH and PTHrP in the skeleton. PTH action can also be analyzed in a pharmacological mode. Administration of PTH leads within minutes to a lowering of calcium caused by uptake of the mineral into bone cells followed by increased mobilization of calcium from the mineral phase into the bloodstream.[46,47] The precise mechanisms responsible for these rapid bidirectional changes have not yet been elucidated, although clearly a major pathway for calcium release from bone involves osteoclasts; these cells undergo multiple cellular changes involving the activation of cellular transporters and pumps, as well as the secretion of enzymes such as cathepsin K and collagenases. Activation of the PTHR-1 in osteocytes also leads to release of calcium from the matrix surrounding osteocytes; the relative roles, quantitatively, of this osteocytic osteolysis versus osteoclastic osteolysis in responses to PTH is a focus of current research.

An additional insight regarding the effects of PTH actions on bone cells can be appreciated through results seen when PTH is used as a therapy for osteoporosis. Daily administration of PTH, i.e., given intermittently, increases bone mass by stimulating bone formation, an action that involves a complex set of cellular responses affecting principally stromal cell/osteoblast proliferation, differentiation, and cellular actions, as well as actions on osteocytes. On the other hand, continuous PTH administration *in vivo* leads to decreased bone mass. In this situation both bone formation and bone resorption are stimulated, but the latter effect is predominant. The pathologic condition of hyperparathyroidism is an example of this effect (see Chapters 54 and 51).

Effects on Osteoblasts. PTH actions on mature osteoblasts, which express the PTHR-1, involve a number of signaling pathways with complex interactions. PTH activates the cAMP/PKA and multiple additional signaling pathways, including the calcium/PKC pathway, the Wnt/beta-catenin pathway, and the mitogen-activated protein kinase pathway. Such potential for signaling diversity likely contributes to the complex patterns of direct and indirect responses that occur in the target cells of bone tissue. The upstream signaling events eventually lead to modulation of the actions of genes crucial for osteoblast differentiation, function, cell division, and apoptosis. A remarkable number of cellular activities of osteoblasts are influenced by PTH, including cellular metabolic activity, ion transport, cell shape, gene transcriptional activity, and secretion of multiple proteases. Among these actions are critical cellular responses including direction of precursor cells into the osteoblast lineage under the influence of Runx2, beta-catenin, and osterix. PTH action promotes osteoblast differentiation in part by promoting exit from the cell cycle. In addition to effects on cell proliferation, PTH controls cell survival by promoting inactivation of the proapoptosis factor BAD and upregulation of the cell survival factor Bcl2.

The salt-inducible kinase (SIK) family of proteins have recently been discovered to play critical roles in mediating both the anabolic and catabolic, as well as the developmental effects of PTHR-1 signaling in the skeleton, particularly in osteocytes, as described further in the following section.[48-50] Recent lineage tracing studies performed in mice that permit tracking, using genetically encoding fluorescent labels, of all descendants of a specifically targeted type of stem cell, reveal that PTH treatment stimulates the awakening of quiescent bone lining cells and hence their transformation into active osteoblasts. PTH also induces the progression of preosteoblastic mesenchymal stem cells along the osteoblast lineage pathway, while preventing their progression along an alternate pathway of adipogenesis.[51-54] The beta-catenin–Wnt ligand signaling pathway plays a key role in mediating responses in osteoblastic cells downstream of PTHR-1 signaling, although some of these effects likely occur indirectly through the direct downregulation by PTHR-1 signaling of expression in osteoblasts and or osteocytes (see later) of the *SOST* gene, which encodes the Wnt pathway inhibitor protein sclerostin.[55] Mature osteoblasts on the bone surface secrete collagen and other elements of the bone matrix (osteoid) and also direct the mineralization of osteoid. These critical steps, as well as the multiple factors in addition to PTH that influence the process, are thoroughly reviewed in Chapter 51.

Effects on Osteoclasts. Multiple factors, local and systemic, are involved in osteoclast generation and activity in addition to PTH (see Chapters 51). Regarding PTH actions, it is generally agreed that osteoclasts lack PTH receptors, and hence actions of PTH are indirect through stimulation of cytokines from osteoblasts and osteocytes. Osteoblasts and osteocytes (see later) produce RANKL, a membrane-associated or soluble, secreted protein with homology to the family of tumor necrosis factors (TNFs), and PTH can stimulate production of this cytokine in these cells.[50,56,57]. RANKL is a critical regulator of osteoclast function, directing differentiation of osteoclast precursors into mature bone-resorbing osteoclasts. These effects of RANKL are mediated through RANK, a member of the TNF receptor family, that induces the differentiation of osteoclast precursors into mature bone-resorbing osteoclasts upon cell-to-cell contact or by binding soluble RANKL (in the presence of macrophage colony-stimulating factor). An additional feedback regulator involved in the balance of bone formation and bone resorption is osteoprotegerin (OPG), a soluble protein with homology also to the TNF receptor family that acts as a decoy receptor and thus binds and inactivates RANKL.[58] PTH inhibits OPG production by osteoblasts. Transgenic expression of OPG leads to impaired osteoclastogenesis and thus to osteopetrosis, whereas genetic ablation of OPG leads to bone loss. Ablation of the gene for RANKL or the receptor, RANK, also leads to osteopetrosis.

Effects on Osteocytes. Osteocytes are the most numerous cells in bone, and there is a growing appreciation of the central biological role they play, not only in bone turnover but also as a source of circulating factors critical in calcium and phosphate homeostasis. Osteocytes are present throughout bone, encased within the mineral matrix.[59,60] However, they develop numerous dendritic processes, which permit communication with one another and with the vasculature and cells on the bone surface. Osteocytes are the key cells in bone that sense and respond to mechanical forces, which lead to changes in bone mass. They are also responsive to PTH, as well as other circulating hormones and locally produced cytokines that contribute to the control of bone mass.[61,62] The role of PTH action in osteocytes in controlling bone remodeling is demonstrated by the marked reduction in bone mass, particularly in the trabecular compartment, seen in mice that have osteocyte-selective deletion of the PTHR-1. Conversely, expression of a constitutively active PTHR-1 specifically in osteocytes leads to a high bone mass phenotype. Osteocytes produce a number of important proteins, many of which are secreted, that are involved in skeletal homeostasis and mineral ion homeostasis. One PTH-sensitive factor that plays a key role in controlling bone metabolism is sclerostin, encoded by the *SOST* gene. Sclerostin acts as a competitive inhibitor of Wnt receptor signaling, and reductions in sclerostin production lead to expansions in osteoblast populations and marked increases in bone mass.[55] The suppression of *SOST* gene expression is thus a major mechanistic component of the anabolic actions of PTH.

A key mechanistic link in the signaling pathway by which PTH reduces *SOST* expression in osteocytes was recently shown to involve the SIK family of proteins.[49,50] In response to PTHR-1–mediated activation of the cAMP/PKA pathway, SIK-2 is specifically phosphorylated by PKA, and this inhibits SIK-2 kinase activity. This, in turn, leads to a decrease in the phosphorylation states of SIK-2 target proteins, which include members of the class 2a family of histone deacetylases (HDACs). The consequent decreased phosphorylation of HDAC proteins causes them to translocate from the cytoplasm to the nucleus, where they act to control the expression of a variety of genes, including *SOST*. PTH-induced SIK-2 phosphorylation thus leads to reduced levels of phosphorylated HDAC-4 and HDAC-5, and hence an increase in the translocation of HDAC-4/5 to the nucleus and their subsequent complexing with certain transcriptional regulators, such as MEF2C, at a distal *SOST* gene enhancer to thus inhibit *SOST* expression. The critical role that SIK proteins play in mediating the anabolic effects of PTHR-1 signaling is demonstrated by two findings. First, treatment of rodents with a small-molecule SIK inhibitor induces increases in bone mass similar to those seen with PTH treatment.[48] Secondly, mice engineered to have genetic ablation of SIK-2 and SIK-3 in mature osteoblasts exhibit a striking increase in bone mass that resembles closely the increase seen in mice expressing a constitutively active PTHR-1 mutant.[49]

In parallel to *SOST* gene regulation, the SIK proteins also mediate the PTH-induced induction of *RANKL* gene expression in osteocytes, and thus act as critical regulators of an important driver of osteoclastogenesis.[50] In this case, instead of HDACs, the SIK-2 target protein that becomes less phosphorylated upon activation of PTHR-1 signaling is the cAMP response transcriptional coactivator 2, CRTC2, which then translocates to the nucleus and activates the *RANKL* gene promoter.

KEY POINTS

- Parathyroid hormone (PTH) acts on cells of the osteoblast lineage to induce changes in the expression of multiple genes involved in calcium and bone metabolism, such as *RANKL* and the gene encoding sclerostin. The salt-inducible kinase family of proteins are key downstream mediators of PTH signaling in bone cells.

MOLECULAR PROPERTIES OF THE PARATHYROID HORMONE RECEPTOR TYPE-1

Gene Structure, Protein Topology, and Evolution

The PTHR-1 belongs to a distinct subgroup of GPCRs called the class B GPCRs, which is comprised of 15 receptors, including those for glucagon, GLP-1, calcitonin, and several other peptide hormones that are each similar in size to PTH(1–34).[63] The gene encoding the human PTHR-1 is located on chromosome 3p and spans at least 20 kb of genomic DNA. The gene consists of 14 coding exons and at least three noncoding exons.

The size of the coding exons in the human gene ranges from 42 bp (exon M7) to more than 400 bp (exon T), and the introns vary in length from 81 bp (intron between exons M6/7 and M7) to more than 10,000 bp (intron between exons S and E1). Two promoters for the PTHR-1, P1 and P2, have been described in rodents. The activity of P1 is mainly restricted to the adult kidney, while that of P2 is detected in several fetal and adult tissues, including cartilage and bone.

The human PTHR-1 receptor protein is 593 amino acids in length, and consists of a 22–amino acid N-terminal signal peptide that is removed during receptor synthesis. The general protein topology is defined by a relatively large N-terminal extracellular domain (ECD) of approximately 160 amino acids, a TMD containing seven membrane-spanning helices with interconnecting loops, and a C-terminal tail of approximately 110 amino acids. In mammals, the PTHR-1 ECD is encoded by five exons: S, E1, E2, E3, and G. Exon S and G encode the signal peptide and a glycosylated segment, respectively. Within segments encoded by exons E1, E3, and G are six conserved cysteines that form a disulfide bond network that establishes the ECD structural fold. Exon E2 encodes a nonconserved 41–amino acid segment that is not essential for function, as it can be deleted or replaced by insertions, such as with sequences encoding green fluorescent protein, without affecting ligand binding or signaling. An equivalent of E2 is absent in the PTHR-1 homologs found in all nonmammalian species, as well as in the PTHR-2 and all other class B GPCRs. The E2 segment of the mammalian *PTHR-1* gene thus likely reflects an evolutionarily recent genetic insertion event. In apparent parallel to the evolutionary history described above for PTH ligands, DNA sequences corresponding to plausible homologs of the PTH receptor have been detected in the genomes of certain protochordates, such as amphioxus and the tunicate sea squirt *Ciona intestinalis,* as well as in some insects.[12,15,16]

Three-Dimensional Structures of the Parathyroid Hormone Receptor Type-1

The first two high-resolution three-dimensional structures of the PTHR-1 were recently reported; one was obtained by x-ray crystallography, and the other by cryo-EM.[64,65] The cryo-EM structure is shown in Fig. 47.5.[65] The structure was obtained as a complex of the receptor bound to a long-acting PTH ligand (LA-PTH; discussed further in a later section of this chapter) and coupled to a heterotrimeric G protein, Gsα/β/γ. The protein components were produced in SF-9 insect cells, and the complex was assembled in a discoid lipid micelle. The PTHR-1 structure determined by x-ray crystallography used an engineered PTHR-1 construct that contained several thermostabilizing mutations, which resulted in a loss of signaling capacity, and the PTHR-1 was bound to an engineered (e)PTH(1–34) analog, but not to a partner G protein.[64] In both studies, the overall structure of the PTHR-1 resembles closely the structures determined for several other class B GPCRs, which includes the glucagon receptor, GLP-1 receptor, secretin receptor, and calcitonin receptor.[63,66-68] The cryo-EM and x-ray crystallography structures of the PTHR-1 represent the receptor in an active, G protein–coupled state, and in a ligand-bound but inactive and G protein–uncoupled state, respectively. Comparing the two structures can thus yield insights into the molecular mechanisms by which PTHR-1 binds a peptide ligand, changes conformation, and couples to G proteins.

KEY POINTS

- X-ray crystallographic and cryogenic electron microscopy structures reveal that the parathyroid hormone 1–34–based ligand binds to parathyroid hormone receptor type-1 as a linear alpha-helix, with its C-terminal 15–34 region docked to the receptor's N-terminal extracellular domain and its N-terminal ~1–14 region projecting down into the core of the receptor's heptahelical transmembrane bundle. Upon activation, the cytoplasmic surface of the receptor opens to allow G protein coupling.

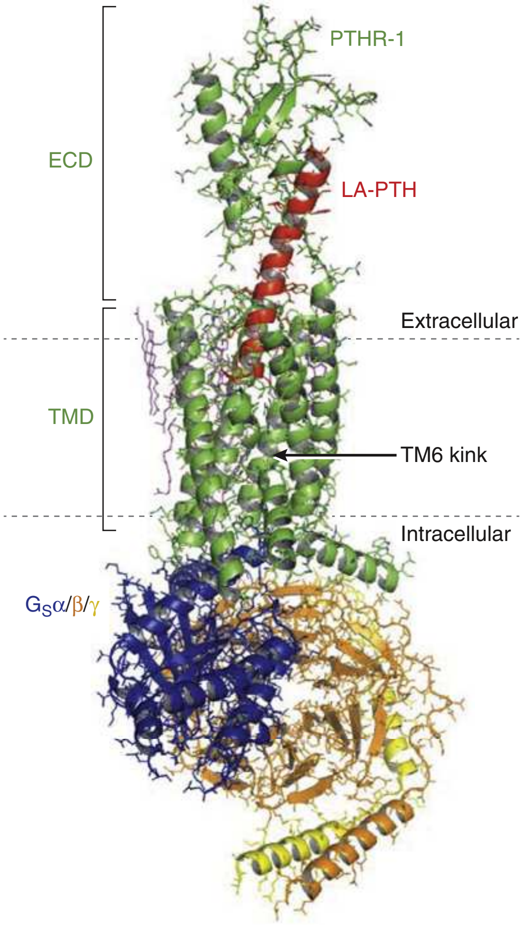

Fig. 47.5 Structure of the parathyroid hormone (PTH) receptor type-1 (PTHR-1) in complex with long-acting (LA)-PTH and Gsα/β/γ. Shown is the structure of the PTHR-1 bound to the LA-PTH, which is a hybrid peptide consisting of the M-PTH(1–14) segment joined to a modified PTH-related peptide(15–36) segment and coupled to a heterotrimeric G protein. The structure was determined by cryogenic electron microscopy at a global resolution of 3.0 Å. The protein backbones are shown in ribbon format, and amino acid sidechains are shown as sticks. The receptor *(green)* is comprised of an N-terminal extracellular domain (ECD) and a heptahelical TMD bundle region. The ligand *(red)* binds as a linear alpha helix, with its C-terminal (15–36) portion contacting the ECD, and its N-terminal (1–14) portion entering into the core of the TMD bundle. Interactions between the N-terminal residues of PTH and residues within the TMD core induce a kink in transmembrane helix 6 (TM6) specifically at the Pro415–Gly418 segment, which leads to an outward movement of the cytoplasmic terminus of TM6 and an opening in the receptor that enables coupling to the G protein trimer. The G protein subunits are Gsα *(blue)*, β *(orange)*, and γ *(yellow)*. Lipid components of the micelle used for assembling the complex are shown in purple. The model is based on the studies reported in[65] and was generated using the protein database file 6NBF and Pymol modeling software.

Mechanisms of Ligand Binding and Activation at the Parathyroid Hormone Receptor Type-1. The basic structure of the PTHR-1 consists of the N-terminal ECD region, which adopts a beta sheet–helix–beta sheet protein fold with a central groove, and a TMD region, which utilizes the classical heptahelical bundle motif present in all GPCRs. The TMD contains an extracellularly exposed pocket that accommodates the key portion of the ligand that activates the receptor. In both the x-ray crystallography and cryo-EM structures, the PTH peptide binds as a continuous alpha-helix with its C-terminal portion docked to the central groove of the ECD and its N-terminal portion projecting downward into TMD pocket, such that residue 1 of PTH is positioned at the approximate center of the TMD bundle and midway between the inner and outer surfaces of the plasma membrane. The total ligand–receptor contact surface area is extensive and ranges the full length of the ligand. Most, if not all, of the numerous intermolecular sidechain and backbone interactions that occur likely contribute to the overall affinity and stability of the complex.

A key difference between the inactive and active state structures of the PTHR-1, also observed in all other class B GPCR structures obtained in active and inactive conformations, is a pronounced kink and partial unfolding in the midsection of transmembrane helix (TM) 6 in the active-state receptor, whereas TM6 is fully helical in the inactive-state receptor (Fig. 47.5). The TM6 kink is centered at the segment Pro415–Gly418, which represents the PXXG motif that is highly conserved in the class B GPCRs. As proline and glycine are helix destabilizing residues, the PXXG motif likely mediates a key step in the PTHR-1 activation process, i.e., the partial unraveling and bending of TM6 upon binding of an agonist ligand. The Pro415–Gly418 segment thus serves as a molecular switch that acts to shift the receptor between inactive- and active-state conformations.

The precise mechanisms of ligand-induced activation remain to be elucidated, but one ligand residue that seems to be involved is Glu4, which is highly conserved in PTH and PTHrP ligands. Glu4 contacts several receptor residues near or just above the PXXG motif, specifically, Tyr195 in TM1, Arg233 in TM2, and Asn448 in TM7.[69] These residues form a conserved central polar network that likely rearranges upon interaction with the negatively charged carboxylate of Glu4 to thereby relay conformational changes to the PXXG motif. As a result of bending at the PXXG segment, the lower, cytoplasmic portion of TM6, as well as those of TM7 and TM5, move outward to open a cavity on the cytoplasmic face of the receptor that is then used for docking a G protein, thus establishing the ligand–receptor–G protein ternary complex.

A second PTHR-1 structural motif that plays a key role in controlling receptor activation is a distinct polar network formed at the cytoplasmic base of the TMD bundle. This motif involves four residues: His223 in TM2, Glu302 in TM3, Thr410 in TM6, and Tyr459 in TM7, which are again highly conserved in the class B GPCRs. This so-called HETY motif acts as yet a second relay switch that directly controls the outward movements of the lower portions of the TMD helices that is required for G protein coupling, as described above. Mutations impacting this HETY motif in the PTHR-1 have been identified in patients with Jansen's metaphyseal chondrodysplasia (JMC), which is discussed in a later section of this chapter.

Conformationally Selective Parathyroid Hormone Ligands and Prolonged Signaling

A series of kinetic binding and signaling assays performed using various PTH and PTHrP ligand analogs has shown that the PTHR-1 can adopt different protein conformations and thus be selectively bound by structurally distinct PTH peptide ligand analogs to induce different types of signaling responses in target cells.[70-72] A noteworthy ligand in this regard is LA-PTH. LA-PTH is a hybrid peptide comprised of a modified PTH(1–14) sequence joined to a modified PTHrP(15–36) sequence. LA-PTH and similar analogs mediate prolonged cAMP signaling responses in cells due to a capacity to bind with high affinity and stability to the G protein–uncoupled PTHR-1 conformation, called R^0. The functional data suggest that such R^0 complexes can, over time, convert to the G protein–coupled, active-state conformation, called RG, to thereby produce extended signaling responses.[71,72] Of further note, fluorescent ligand-tracking studies in cells show that these analogs move with the PTHR-1 into internalized vesicles during the times of prolonged signaling.[69,70] These observations suggested that the internalized PTHR-1–ligand–G protein complexes remained active after internalization, rather than dissociating and terminating signaling, as generally would be expected from classical GPCR theory. Evidence to support such prolonged endosomal signaling has since been demonstrated for at least several other class B GPCRs. In contrast to LA-PTH, other PTH peptides, including PTHrP(1–36), M-PTH(1–14), and abaloparatide, a PTHrP(1–34) analog used to treat osteoporosis (see later), bind poorly to the R^0 conformation of the PTHR-1, and thus mediate relatively transient signaling responses in cells, due to their relative selectivity for the RG conformation.[73]

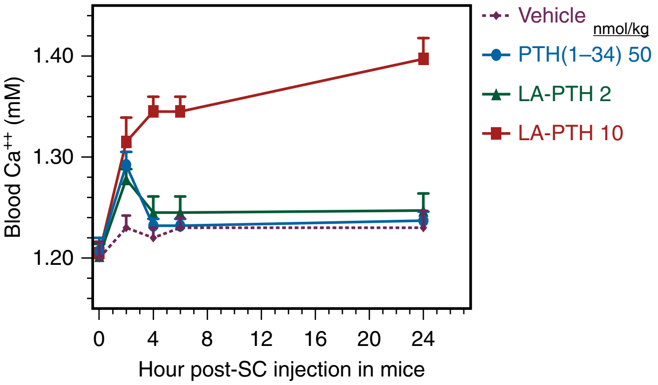

Fig. 47.6 Properties of a long-acting parathyroid hormone (PTH) analog (LA-PTH) *in vivo*. Shown are the capacities of PTH(1–34) and LA-PTH, which is comprised of a modified M-PTH(1–14) segment joined to a modified PTH-related peptide(15–36) segment, to stimulate increases of blood ionized calcium in mice following a single subcutaneous (SC) injection. PTH(1–34) was injected at a peptide dose of 50 nmol/kg, and LA-PTH was injected at doses of 2 and 10 nmol/kg; vehicle was injected as a control. The long duration of the calcemic responses induced by LA-PTH, relative to that of PTH(1–34), correlates with the prolonged cyclic 3′,5′-adenosine monophosphate response induced by LA-PTH in cells, and with the greater affinity with which it binds to the R^0 conformation of the PTH receptor type-1. (Adapted from Maeda A, Okazaki M, Baron DM, et al. Critical role of parathyroid hormone (PTH) receptor-1 phosphorylation in regulating acute responses to PTH. *Proc Natl Acad Sci U S A*. 2013;110:5864–5869.)

The biological relevance of such ligand-directed conformational selectivity at the PTHR-1 remains to be established. A potential clinical relevance, however, has been indicated, most notably by the capacity of LA-PTH to induce sustained elevations in serum calcium when injected into animals (Fig. 47.6).[71,72,74] Accordingly, LA-PTH has recently entered into a phase I clinical trial to evaluate the analog as a potential alternative therapy for hypoparathyroidism, a disease that requires careful therapeutic control of blood calcium levels for extended periods.[75] Abaloparatide, a PTHrP(1–34) analog in use as an osteoporosis therapy,[76] binds selectively to RG and mediates transient cAMP signaling responses in cells.[73] The distinct profile of receptor conformation selectivity exhibited by this peptide may facilitate its efficacy in osteoporosis patients, as PTH ligand–induced increases in bone mass are well known to be dependent on a pulsatile, rather than continuous, mode of exposure, although the underlying mechanisms for these effects are not fully understood.[77]

Disease Mutations in the PTHR-1 and its Ligands

Both gain-of-function and loss-of-function mutations in the PTHR-1 have been linked to disease pathologies that involve disturbances in skeletal development, and in some cases calcium homeostasis. Gain-of-function mutations have been identified in patients with JMC.[78] Although ultrarare, all JMC patients to date (n ≈ 25) have a heterozygous missense mutation that impacts the HETY motif in the PTHR-1 TMD region described earlier. This observation strikingly highlights the significance of the HETY motif in maintaining proper PTHR-1 function. The JMC mutations are: His223→Arg in TM2, which is the most common JMC allele, Thr410→Pro/Arg in TM6, and Ile458→Arg/Lys. The JMC mutations likely perturb the H-bond and electrostatic interaction network in the HETY motif to cause an increase in the rate of conversion of the receptor from the inactive state to the active state in the absence of a bound agonist ligand, and hence an excess in basal levels of cAMP in cells of bone, kidney, and growth-plate cartilage, and ultimately the severe abnormalities in skeletal development and mineral ion homeostasis, including dwarfism and hypercalcemia, that characterizes the JMC phenotype.[78]

Several pathologic conditions, again rare, have been linked to loss-of-function mutations in the PTHR-1. Blomstrand osteochondrodysplasia (BOCD), is a recessive neonatal lethal disorder characterized by premature ossification of the skeleton, as well as defects in development of the lung, aorta, and breasts. The physical defects and neonatal death associated with BOCD parallel those seen in mice in which the *PTHR-1* gene is ablated. The mutations of BOCD are homozygous or compound heterozygous changes that impact the structure or function of the PTHR-1 protein, e.g., of conserved Pro132 to Leu, or the splicing or stability of the mRNA. Heterozygous loss-of-function mutations in the PTHR-1, including Pro132Leu, have been identified in patients with familial primary failure of tooth eruption,[79] which correlates with mouse studies showing a clear role for PTHR-1 signaling and the paracrine actions of PTHrP in tooth development.[80] Ollier disease, a developmental disorder characterized by the presence of multiple enchondromas, has been linked to several heterozygous PTHR-1 mutations, including Gly121→Glu, Ala122→Thr, and Arg150→Cys, which are each located in the ECD. Functional assessment in cells of these three mutations suggest that they reduce ligand-binding affinity and/or expression of the receptor, but it remains unclear how the mutations lead to the enchondromas seen in patients.

Disease mutations have also been identified in the genes encoding the ligands PTH and PTHrP. Heterozygous mutations impacting expression or function of PTHrP have been identified in patients with brachydactyly type E, at least some of whom also exhibit tooth eruption failure, short stature, shortened limbs, and/or dysmorphic craniofacial features.[81] These phenotypes are again fully consistent with the critical role that paracrine-acting PTHrP and PTHR-1 signaling play in skeletal development. Mutations impacting PTH function have been found in patients with hypoparathyroidism. The mutations identified include dominant-acting missense mutations in the PTH prepro region, as well as two very rare homozygous missense mutations in the mature PTH polypeptide, Arg25→Cys and Ser1→Pro.[37,82] Here, the hypocalcemia characterizing the disease reflects the critical role that endocrine-acting PTH plays in maintaining calcium homeostasis.

KEY POINTS

- Heterozygous loss-of-function mutations in parathyroid hormone receptor type-1 are associated with a primary failure of tooth eruption, while gain-of-function mutations cause Jansen's metaphyseal chondrodysplasia (JMC), a disease of bone development and mineral ion homeostasis. JMC mutations have been found at only three receptor sites, consistent with the ultrarare frequency of the disease.

Small-Molecule Ligands for the Parathyroid Hormone Receptor Type-1

Several small-molecule ligands have been identified for the PTHR-1. This includes the agonist PCO371 and several antagonist compounds.[83,84] The precise mode of action used by such compounds remains to be elucidated; however, functional studies indicate that PCO371 binds to the TMD portion of the receptor. Although PCO371 binds to the PTHR-1 with a low-micromolar affinity, and is thus much weaker than PTH(1–34), it can be administered orally, whereas PTH peptides must be injected for therapeutic use. Based on this bioavailability and a prolonged pharmacokinetic profile, PCO371 has entered into early-stage clinical testing as a candidate therapy for hypoparathyroidism. These studies should provide further clues as to how new compounds can be developed that function as more potent and orally active agonists or antagonists on the PTHR-1 .

THE PARATHYROID HORMONE RECEPTOR TYPE-2 AND TIP39

The PTH receptor type-2 (PTHR-2) was originally identified by screening a human brain cDNA library for sequences homologous to the PTHR-1, and thus exhibits 51% identity to the PTHR-1 at the amino acid sequence level. The human PTHR-2 exhibits at least some reactivity towards PTH, but it does not bind PTHrP. Further studies on the rat PTHR-2 revealed weak, if any, binding of either PTH or PTHrP. This finding, and the abundant expression of the PTHR-2 mRNA in brain, led to a search for the endogenous cognate PTHR-2 ligand in brain tissue. Fractionation of hypothalamic extracts then revealed such a peptide ligand, which was called tubular infundibular peptide of 39 amino acids, or TIP39. This peptide efficiently binds to and activates both the rat and human PTH2 receptors and is thus presumed to be the natural agonist for the PTHR-2.

TIP39 exhibits weak amino acid sequence homology to the corresponding N-terminal regions of PTH and PTHrP and is extended N-terminally by two amino acids. TIP39 and the PTHR-2 are expressed in brain, testes, and skin. Studies in rodents provide evidence for a neuroendocrine role for the PTHR-2 and TIP39 in mediating pain and stress responses, as well as the lactation response to nursing.[85,86] A paracrine role in the development of the testis is suggested by the finding that male mice lacking the gene for either TIP39 or PTHR-2 are sterile due to a failure in spermatid formation. PTHR-2 and TIP39 are also expressed in keratinocytes, and female mice deleted for the *PTHR-2* gene exhibit a thickened epidermis and increased expression of keratin-14, suggesting a role in keratinocyte differentiation and in the maintenance and/or development of the dermal layer.[87] Genes corresponding to *TIP39* and *PTHR-2* are detected in the genomes of primitive fish, such as the sea lamprey, suggesting an emergence during early vertebrate evolution; however, neither gene is detected in birds.[12,13] No disease phenotype in humans has been linked to the PTHR-2 or TIP39.

SUMMARY

The actions of the N-terminal portion of PTH and PTHrP (or fragments of these regions) are mediated through a single receptor, PTHR-1, a class B GPCR that signals through the cAMP/PKA as well as the inositol triphosphate/calcium/diacylglycerol/PKC pathways. The PTHR-1 is expressed in a variety of fetal and adult tissues. The PTHR-1 in kidney and bone mediates the endocrine actions of PTH in mineral ion homeostasis, while in the growth plates and other developing tissues it mediates the autocrine/paracrine actions of PTHrP. Mutations in the PTHR-1 or its ligands are associated with several diseases of calcium homeostasis and skeletal development. The PTHR-1 adopts multiple conformational states, which can be selectively bound by structurally distinct peptide ligands to achieve disparate biological outcomes. The PTH-2 receptor and TIP39 appear to mediate neuroendocrine and potentially developmental functions but are still not well characterized biologically. A potential biological role for the C-terminal regions of either PTH or PTHrP has not been fully defined.

KEY POINTS

- Parathyroid hormone-related protein (PTHrP) was originally discovered as a cause of elevated calcium levels in patients with cancer.
- PTHrP is part of a small gene family related to parathyroid hormone (PTH).
- Both PTH and PTHrP bind to and activate the same G protein–coupled receptor known as the type 1 PTH/PTHrP receptor.
- PTHrP is expressed in many tissues during development and has been shown to be critical for the normal development of bones, cartilage, teeth, and the mammary gland.
- Mammary gland–derived PTHrP has also been shown to contribute to the regulation of calcium and bone metabolism during lactation.
- PTHrP contributes to the development and/or progression of breast cancer.
- PTHrP can regulate smooth muscle cell tone and contraction in blood vessels and in the uterus.
- PTHrP can regulate pancreatic β cell mass and may be useful in the treatment of diabetes.
- A synthetic PTHrP analog was approved for the treatment of postmenopausal women with osteoporosis.

The discovery of parathyroid hormone-related protein (PTHrP) was anticipated in 1941, when Fuller Albright postulated that tumors may produce a parathyroid hormone (PTH)-like humor.[1] We now understand that PTHrP and PTH are related molecules that can both stimulate the same type 1 PTH/PTHrP receptor (PTH1R).[1,2] As a result, when PTHrP is secreted by tumors, it mimics its cousin, PTH, and leads to excessive bone resorption and hypercalcemia. After its discovery, it became obvious that PTHrP was widely expressed, prompting efforts to understand its normal functions. Over the past 34 years, we have defined critical functions in some specific tissues, but it is remarkable how little we really understand of its function(s) in all the various tissues that produce PTHrP. The goal of this chapter is to outline the basic facts of PTHrP biology, especially its contributions to physiology and pathophysiology.

THE *PTHRP* GENE AND THE *PTH/PTHRP* GENE FAMILY

In humans, PTHrP is encoded by a single-copy gene (the official gene symbol is *PTHLH*) containing eight exons and three promoters that is located on the short arm of chromosome 12 (Fig. 48.1).[2] Alternative splicing at the 3′ end of the gene gives rise to three different classes of mRNAs coding for specific translation products of 139, 141, or 173 amino acids, each of which contains the same 36–amino acid prepro, or signal, sequence and the same initial 139 amino acids. Each class of mRNA also contains AU-rich regulatory elements within the 3′ untranslated region that are associated with rapid but regulated mRNA turnover.[2] The physiologic significance of the different classes of PTHLH transcripts remains unclear, and in rodents and lower vertebrates such as birds and fish PTHrP 1–173 does not exist.[2,3] Two studies examining breast cancer cells have suggested that certain patterns of promoter usage and/or splicing patterns may be associated with different behaviors of the cancer cells, such as the likelihood metastasizing to bone or their invasive behavior.[4,5]

PTHLH mRNA is also regulated by microRNAs. miR-182-5p and miR-195 have been shown to downregulate *PTHLH* mRNA and PTHrP protein levels, altering the differentiation and function of cultured human chondrocytes.[6,7] Moreover, compared with healthy tissue, miR-195 levels were shown to be increased in tibial plateaus samples from patients with osteoarthritis, which demonstrated reduced PTHrP mRNA and protein levels. Given that PTHrP has been suggested to prevent osteoarthritis, targeting miR-195 could be a novel therapeutic approach for the treatment of this condition.[6]

The *PTHLH* and *PTH* genes share structural elements and sequence homology, establishing that they are both members of the

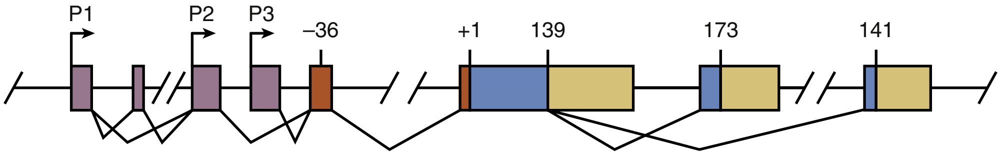

Fig. 48.1 **Diagram of the *PTHLH* gene.** The gene consists of eight exons *(colored boxes).* The 5′ untranslated region is represented in *purple*, the prepro sequences in *red*, the coding region in *blue*, and the 3′ untranslated region in *yellow*. The three promoter regions are denoted by *arrows,* and the possible splicing patterns are noted by the *lines* connecting the different exons.

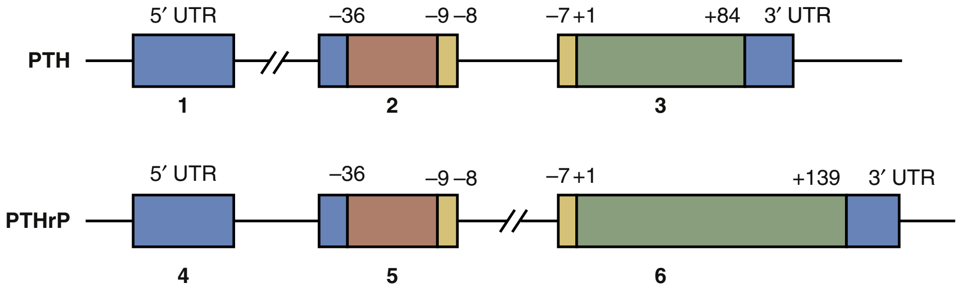

Fig. 48.2 **Side-by-side comparison of the prepro and coding regions of the *PTH* and *PTHrP* genes.** Note that the exon/intron configuration of both genes is identical for those portions encoding the signal peptides and N-terminal portions of each protein. *UTR,* Untranslated region.

same gene family.[1,2] The exon/intron organization of that portion of both genes encoding the prepro sequences and the initial portion of the mature peptides is identical (Fig. 48.2). Furthermore, there is high sequence homology at the N-terminal portion of both genes, such that the peptides share eight of the first 13 amino acids and a high degree of predicted secondary structure over the next 21 amino acids. These common sequences allow both peptides to bind and activate the same receptor, known as the *type 1 PTH/PTHrP receptor* (*PTH1R*) explaining the ability of PTHrP to cause hypercalcemia in humoral hypercalcemia of malignancy (HHM).[8] These structural similarities, together with the location of the two genes on related chromosomes in the human genome (short arm of chromosome 11 for *PTH*; short arm of chromosome 12 for *PTHLH*), indicate that the two genes likely arose from a common ancestor via gene duplication. The PTH family also contains the *PTH-L* gene and the more distantly related tuberoinfundibular peptide 39 (*TIP39*) gene. All of these genes were derived from a common ancestor and emerged concurrent with the evolution of vertebrates.[3] Furthermore, fish have two *Pth* genes, two *Pthlh* genes, one *Tip39* gene, and one *Pth-l* gene; amphibians have one *Pth* gene, one *Pthlh* gene, and one *Pth-l* gene; and mammals only retain one *PTH* gene and one *PTHLH* gene.[3] Thus, PTHrP is a member of an ancient family of PTH-like peptides that appears to be larger and more diverse in lower vertebrates than in mammals. The evolutionary relationships between members of the PTH gene family are also discussed in Chapter 47. There is a high degree of homology within PTHrPs of different species for the first 111 amino acids. There is less homology between amino acids 111 and 139, and PTHrP sequences from 141 to 173 are specific to the human gene.[2]

KEY POINTS

- Parathyroid hormone-related protein is part of a small gene family related to parathyroid hormone.

PTHLH mRNA has been found in almost every organ. A multitude of different hormones and growth factors have been described to regulate the transcription and/or stability of *PTHLH* mRNA. This chapter will not list all of these factors but will discuss the regulation of PTHrP in different cell types as part of the discussion of the functions of PTHrP in specific organs. The reader is referred to other reviews for a more comprehensive cataloging of the factors described to regulate PTHrP expression.[2,9] There are several broad themes to emphasize at this juncture. First, PTHrP is generally expressed at much higher levels and in many more sites during fetal development than it is during adult life.[2] Second, during development, PTHrP is expressed in close association with the PTH1R receptor (discussed later) in a “hand-in-glove” pattern in which PTHrP is produced by forming epithelial organs and the PTH1R is produced by the enveloping mesenchyme (Fig. 48.3).[10] Third, analogous to PTH in the parathyroid glands, the calcium-sensing receptor (CaSR) has been found to regulate *PTHrP* gene expression in many cells.[11] Finally, *PTHLH* mRNA levels are induced by mechanical deformation in various types of smooth muscle cells[2] and by cells in the osteoblast lineage.[11]

POSTTRANSLATIONAL PROCESSING OF PARATHYROID HORMONE-RELATED PROTEIN

The primary translation product of PTHrP undergoes posttranslational processing events to produce an overlapping series of biological peptides.[2] The basic outline of PTHrP processing was elucidated in the first decade after its discovery, but little work has been performed in this area for many years. As a result, the full details of cell-specific PTHrP processing and the biological significance of the different PTHrP peptides remain only partly understood. The primary translation product predicted by the *PTHLH* cDNAs contains multiple potential processing sites, consisting of clusters of basic amino acids in pairs, triplets, or quadruplets. It has been shown that an arginine at position 37 serves as a cleavage site to generate PTHrP 1–36, which is secreted from many cell types.[2] The N-terminus is necessary for interaction with the PTH1R and PTHrP 1–36 appears fully able to bind and activate this receptor. Moreover, PTHrP 1–36 can be further processed by matrix

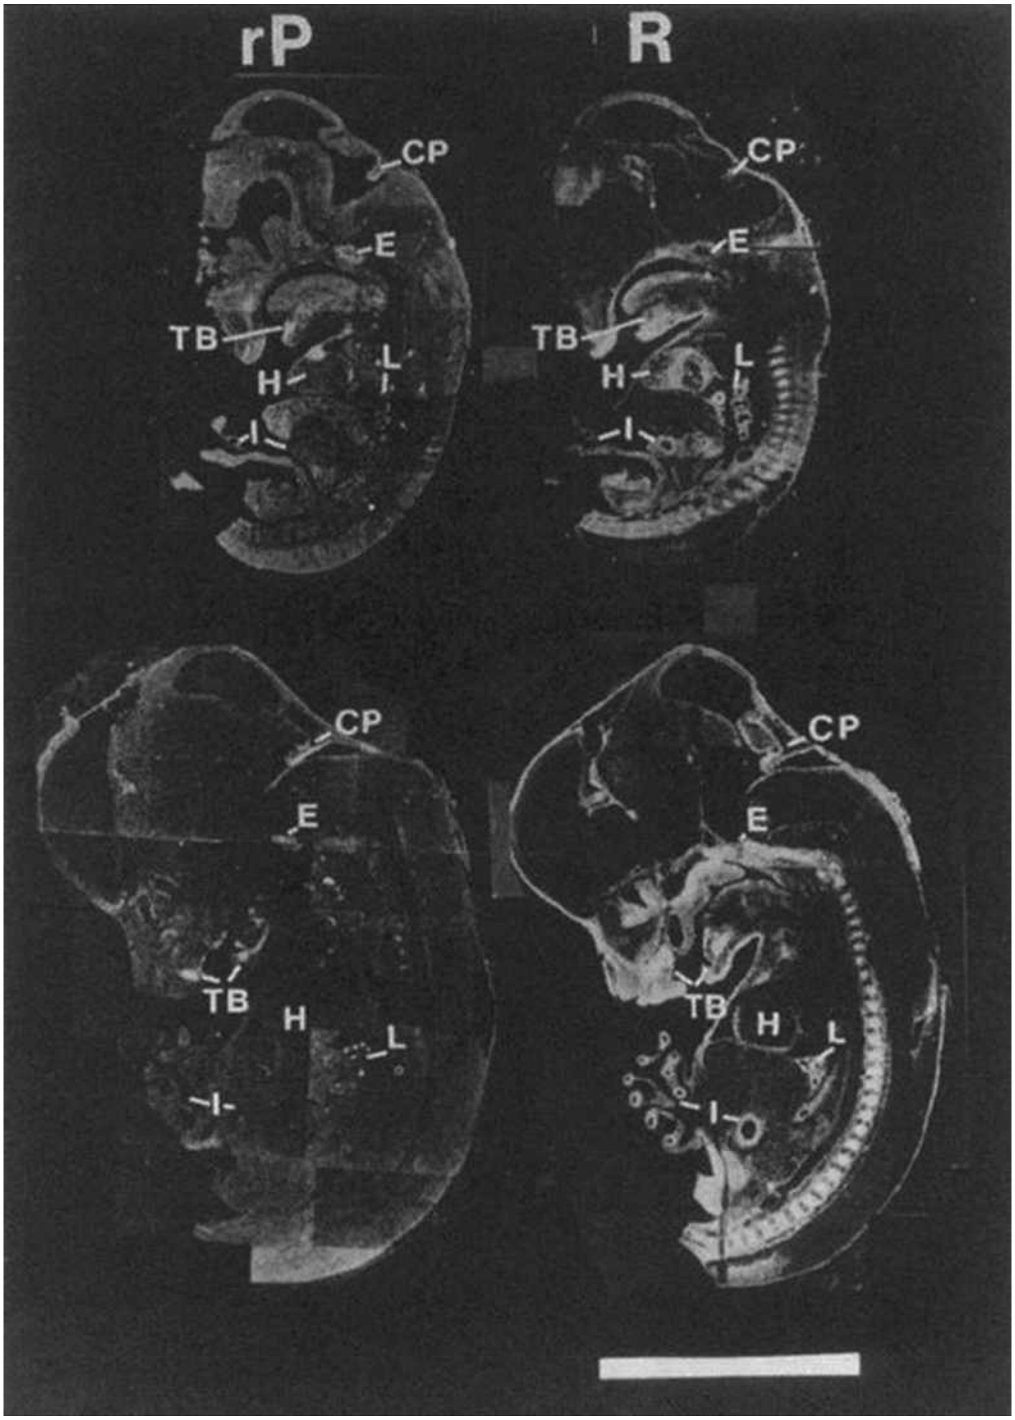

Fig. 48.3 Patterns of expression of parathyroid hormone-related protein (PTHrP) and type 1 parathyroid hormone/ parathyroid hormone-related protein receptor (PTH1R) mRNA in rat fetuses at embryonic day (E) 15 *(top)* and E16 *(bottom)*. Shown are dark-field photographs of ^{35}S-labeled complementary RNAs. Note that PTHrP is expressed in forming epithelial organs, and the PTH1R is expressed in the surrounding mesenchyme. *CP,* Choroid plexus; *E,* inner ear; *TB,* tooth bud; *L,* lung; *H,* heart; *I,* intestine; *rP*, parathyroid hormone-related protein; *R,* type 1 parathyroid hormone/ parathyroid hormone-related protein receptor. The scale bar represents 5000 microns. (Reproduced from Lee K, Deeds JD, Segre GV. Expression of parathyroid hormone-related peptide and its receptor messenger ribonucleic acids during fetal development in rats. *Endocrinology*. 1995;136:453–463.)

metalloproteinases to yield a stable product, PTHrP 1–17, secreted by rat and human cancer cells and still capable of activating the PTH1R to direct osteoblast differentiation and osteogenesis.[12] Longer forms of N-terminal–containing PTHrP are secreted from keratinocytes and mammary epithelial cells and circulate in patients with cancer and during lactation.[11] It is not clear what defines the C-terminus of these peptides, nor is it clear whether they differ in biological activity from PTHrP 1–36. Adding additional complexity, N-terminal PTHrP secreted by keratinocytes has been shown to be heavily glycosylated.[13] Furthermore, a recent study suggested that osteocytes secrete only full-length PTHrP without any cleavage products.[14] Clearly, there is great heterogeneity in the forms of PTHrP that contain the N-terminus of the molecule and that have the ability to interact with the PTH1R. Presumably, a similar variety of PTHrP peptides exists *in vivo*, but this question remains understudied and, therefore, the answer remains unknown.

KEY POINTS

- Parathyroid hormone-related protein undergoes posttranslational processing events to produce an overlapping series of biological peptides.

Cleavage of PTHrP at downstream sites leads to the secretion of midregion peptides including amino acids 38 to 94, 38 to 95, and 38 to 101.[2] The biology of these peptides is unclear, but the midregion of PTHrP stimulates placental calcium transport and modulates renal bicarbonate handling, and this portion of the molecule contains nuclear localization signals (see later).[15] Finally, C-terminal fragments consisting of amino acids 107 to 138 and 109 to 138 have been described. These peptides have been suggested to inhibit osteoclast function and stimulate osteoblast proliferation.[2,15] It is likely that the posttranslational processing of PTHrP is controlled for specific physiologic purposes, but, until the biology of specific PTHrP peptides (apart from those that contain the N-terminus) is better appreciated, little additional effort is likely to be expended on elucidating the specifics of PTHrP processing.

PARATHYROID HORMONE-RELATED PROTEIN RECEPTORS

N-terminal PTHrP binds to and activates the PTH1R a member of class B of the large family of seven transmembrane-spanning domain, G protein–coupled receptors.[9] This receptor is discussed at greater length in Chapter 47. Although binding of PTHrP 1–36 or PTH 1–34 to the receptor occurs via similar mechanisms, biochemical and biophysical data have demonstrated subtle differences in the binding of PTH versus PTHrP to the PTH1R. Binding of PTH favors a conformational state known as G^0, which is relatively stable and allows the receptor to undergo multiple rounds of G-protein activation generating cyclic adenosine monophosphate (cAMP) over a longer period of time. By contrast, the binding of PTHrP 1–36 to the receptor favors a more labile RG conformational state, which does not support multiple rounds of G-protein activation and, thus, generates less cAMP than the binding of PTH.[16] The three-dimensional crystal structures of PTH 1–34 and PTHrP 1–36 bound to the extracellular domain (ECD) of the PTH1R offer a potential explanation for these pharmacologic observations.[17,18] Portions of both peptides from amino acids 14 through 30 form an amphipathic helix, which binds to a specific cleft in the receptor's ECD. However, the α-helix formed by PTH is longer than the one formed by PTHrP, allowing PTH to fit more tightly into the receptor's binding cleft than PTHrP. Interestingly, a recent study showed that full-length PTHrP elicits a more sustained cAMP response than PTHrP 1–36. This action seems to be endocytosis-dependent, because blocking receptor internalization inhibited the cAMP activation response.[19] Thus, while the PTH1R can be activated by either PTH or PTHrP, the receptor appears to be able to tell the difference between the two peptides and, perhaps, even between different forms of PTHrP. These different ligand–receptor interactions may stimulate different biological processes in response to one protein versus the other. This seems to be the case in humans subjected to continuous infusion of PTH versus PTHrP for 3 to 7 days. Subjects became hypercalcemic with lower doses of PTH 1–34 than with PTHrP 1–36.[16] In addition, PTHrP was also less effective than PTH at stimulating the renal 1-α-hydroxylase enzyme and producing 1,25-dihydroxyvitamin D.

KEY POINTS

- Both parathyroid hormone (PTH) and parathyroid hormone-related protein (PTHrP) bind to and activate the same G protein–coupled receptor, known as the type 1 PTH/PTHrP receptor.

In addition to these ligand-specific differences in signaling, studies *in vitro* have suggested that PTH1R signaling can be modulated by other molecules. High extracellular calcium was recently shown to act as an allosteric modulator of the PTH1R prolonging the residence time of ligands on the receptor and, consequently, increasing both the duration of receptor activation and cAMP signaling.[20] In addition, adenosine triphosphate, whose levels were shown to increase in the bone extracellular fluid after mechanical loading, may potentiate PTH and PTHrP-induced adenylyl cyclase activation.[21] Therefore, alterations in the target cell microenvironment that may modulate the pharmacologic effects of PTHrP peptides, are important considerations for understanding PTHrP biology *in vivo*, as well as for strategies to potentiate current and future anabolic therapy for osteoporosis.

NUCLEAR PARATHYROID HORMONE-RELATED PROTEIN

In addition to being secreted and acting on the PTH1R PTHrP can also act within the nucleus. Two pathways through which PTHrP accesses the nucleus have been described: 1) PTHrP directly enters the cytoplasm rather than the endoplasmic reticulum (ER) for secretion; and 2) PTHrP is secreted from cells and then reenters the cytoplasm by endocytosis (Fig. 48.4). Two aspects of the *PTHLH* gene make the first pathway possible. First, *PTHLH* encodes an alternative downstream transcriptional start site that bypasses the signal peptide, allowing PTHrP to avoid secretion and remain in the cell.[15] Second, PTHrP's signal peptide is less hydrophobic than most, weakening its interaction with the signal recognition particle responsible for initiating translocation of the nascent polypeptide chain into the ER lumen.[22] Moreover, the proregion has positively charged residues that may affect the insertion of the growing nascent polypeptide into the ER translocation pore.[23] Either way, once in the cytoplasm, PTHrP shuttles into and out of the nucleus in a regulated fashion. There are classic nuclear localization sequences (NLSs) located between amino acids 84 to 93, and specific proteins have been shown to mediate entry into and export from the nucleus.[15] Importin β1 mediates the entry of PTHrP into the nucleus, in part by displacing PTHrP from microtubules and allowing it to transit the nuclear pore.[15] Nuclear export involves the actions of a related shuttle protein known as CRM1 and appears to involve specific sequences in the C-terminal region of the peptide.[15] Phosphorylation of PTHrP at Thr^{85} by the cell-cycle–associated cyclin-dependent kinase $p34^{cdc2}$ regulates nuclear import in a cell-cycle–dependent fashion.[15]

KEY POINTS

- In addition to being secreted and acting on the type 1 parathyroid hormone/parathyroid hormone-related protein receptor, parathyroid hormone-related protein can also act within the nucleus.

The second pathway through which PTHrP accesses the nucleus is by binding to the PTH1R at the cell surface. In ways that are poorly understood, PTHrP bound to the PTH1R can be internalized and transported into the nucleus.[24] The PTH1R has a potential NLS,

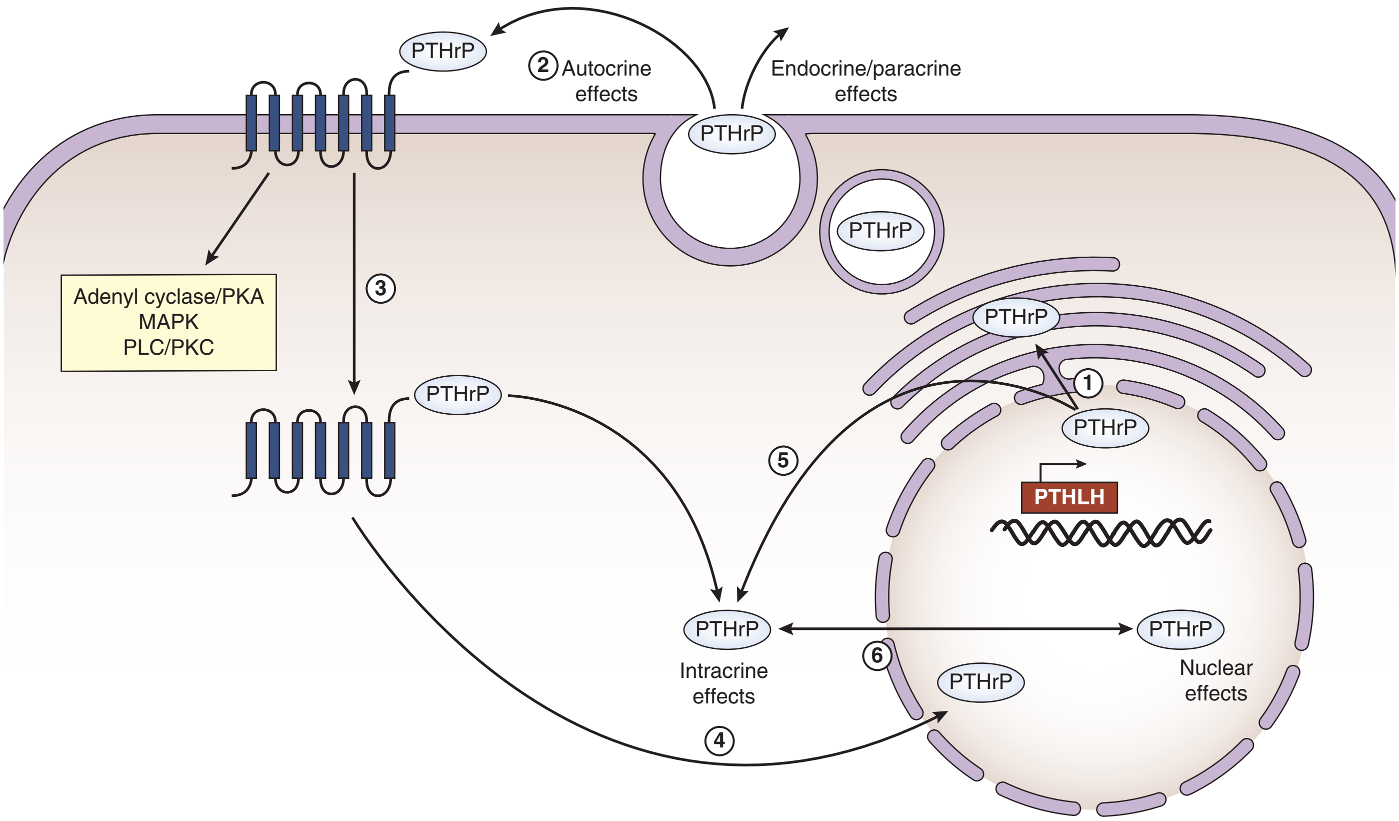

Fig. 48.4 Multiple pathways of parathyroid hormone-related protein (PTHrP) action. After being synthetized, PTHrP can be 1) targeted to the endoplasmic reticulum (ER) and secreted from the cell to act in a paracrine/endocrine or 2) autocrine fashion by binding to type 1 parathyroid hormone/parathyroid hormone-related protein receptor and activating signaling pathways. 3) PTHrP can also be internalized by endocytosis and, once in the cytoplasm, 4) imported to the nucleus. 5) PTHrP can also elude targeting into the ER and directly enter the cytoplasm, remain intracellular to act in an intracrine manner, and then 6) be transported to the nucleus by importin β. *PTHLH,* parathyroid hormone like hormone.

although it is not clear if this mediates active transport of the receptor into the nucleus together with PTHrP.[15] However, this second pathway may allow nuclear PTHrP signaling to operate in a paracrine fashion as well as through a cell autonomous pathway.

The function(s) of nuclear PTHrP are a focus of ongoing investigation, and very little is understood about its actions in the nuclear microenvironment. PTHrP has been shown to bind to RNA and, in some cells, it localizes to the nucleolus, suggesting that it may be involved in regulating RNA trafficking, ribosomal dynamics, and/or protein translation.[15] In cultured cells, nuclear PTHrP influences cell proliferation and/or apoptosis and often appears to oppose the effects of secreted PTHrP. In breast, colon, and prostate cancer cells, the nuclear pathway stimulates cell proliferation, protects cells from apoptosis or anoikis, and stimulates cell migration, while secreted PTHrP inhibits cell proliferation and promotes cell death.[15,25] This has been most carefully studied in vascular smooth muscle cells, where nuclear PTHrP stimulates proliferation by inducing the expression of c-myc and skp2, which, in turn, reduce levels of the cell-cycle inhibitor p27.[26] In contrast, secreted PTHrP has the opposite effects.

Two groups have examined the biology of nuclear PTHrP *in vivo* by replacing the endogenous mouse *Pthlh* gene with truncated versions, encoding PTHrP 1–84 or PTHrP 1–66, that exclude the nuclear localization signals and C-terminus.[27,28] This approach has complicated the interpretation of these experiments somewhat, because it is difficult to know whether the resulting phenotypes are due only to loss of nuclear signaling or also to loss of the C-terminal portion of PTHrP. Nevertheless, in both cases, while loss of nuclear and C-terminal PTHrP did not cause the developmental defects typical of PTHrP or PTH1R knockout mice, it did cause growth failure, premature osteoporosis, reduced hematopoiesis, altered energy metabolism, premature ageing of skin, abnormal brain development and, ultimately, premature death at approximately 2 weeks of age. There was a decrease in the proliferation of chondrocytes, osteoblasts, neurons, skin cells, and bone marrow cells, and an increase in apoptosis or senescence at these sites, as well as in the thymus and spleen. Loss of midregion and C-terminal PTHrP was associated with increased expression of senescence markers such as p21, p27, and $p16^{INK4a}$ and decreased expression of Bmi-1, which is involved in stem/progenitor cell maintenance.[11,29] This phenotype is consistent with the previous observations in cell culture and suggests that nuclear PTHrP may participate broadly in the regulation of cell proliferation and survival, as well as in stem/progenitor cell maintenance or self-renewal. However, experiments in the mammary gland have shown that *Pthlh* gene expression is severely reduced in mammary epithelial cells in PTHrP 1–84 knockin embryos, and that the resulting mammary phenotypes were the result of very low levels of PTHrP.[30] Although both groups documented normal production of PTHrP 1–84 or PTHrP 1–66 in some cell types, this is clearly not the case in all cells. Therefore, some of the reported findings in these mouse models may be due to reduced overall PTHrP production rather than loss of nuclear signaling.

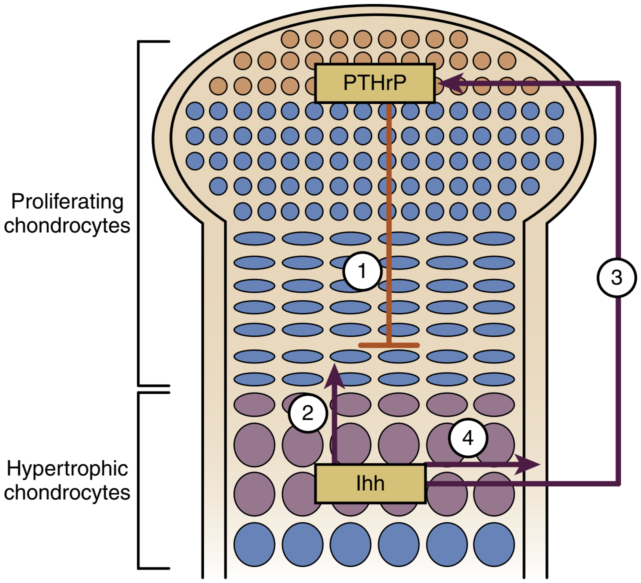

Fig. 48.5 Parathyroid hormone-related protein (PTHrP) and Indian hedgehog (Ihh) act as part of a negative feedback loop regulating chondrocyte proliferation and differentiation. The chondrocyte differentiation program proceeds from undifferentiated chondrocytes at the end of the bone, to proliferative chondrocytes within the columns and then to prehypertrophic and terminally differentiated, hypertrophic chondrocytes nearest the primary spongiosum. PTHrP is made by undifferentiated and proliferating chondrocytes at the ends of long bones. It acts through the type 1 parathyroid hormone/parathyroid hormone-related protein receptor (PTH1R) on proliferating and prehypertrophic chondrocytes to delay their differentiation, maintain their proliferation, and delay the production of Ihh, which is made by hypertrophic cells *(1)*. Ihh, in turn, increases the rate of chondrocyte proliferation *(2)* and stimulates the production of PTHrP at the ends of the bone *(3)*. Ihh also acts on perichondrial cells in order to generate osteoblasts of the bone collar *(4)*. Ihh, Indian Hedgehog (Reproduced from Ansari N, Ho PW, Crimeen-Irwin B, et al. Autocrine and paracrine regulation of the murine skeleton by osteocyte-derived parathyroid hormone-related protein. *J Bone Miner Res*. 2018;33:137–153.)

PHYSIOLOGIC FUNCTIONS OF PARATHYROID HORMONE-RELATED PROTEIN

PTHrP is expressed by many cells, and it has been shown to affect the proliferation, differentiation, and survival of many cell types *in vitro*. This chapter will not attempt to review all of these data. Rather, the discussion will focus on organs in which there are physiologic or genetic data *in vivo* implicating PTHrP in critical aspects of that organ's functions.

The Skeleton

One of the first-described and perhaps best-understood functions of PTHrP is to control the proliferation and differentiation of chondrocytes in the developing growth plate. Animal models of PTHrP overexpression and underexpression have documented that N-terminal PTHrP acts through the PTH1R to coordinate the rate of chondrocyte differentiation in order to maintain the orderly growth of long bones during development.[31] As illustrated in Fig. 48.5, the growth plate consists of columns of proliferating and differentiating chondrocytes that progressively enlarge to prehypertrophic and then hypertrophic chondrocytes. Both the production of new chondrocytes and their enlargement into hypertrophic cells together drive linear growth at the ends of bones. PTHrP is initially produced by cells at the periphery of the condensing mesenchyme that gives rise to the endochondral bones, and PTHrP expression becomes restricted to the ends of the forming bones as development proceeds.[32] The creation of a secondary ossification center after birth splits the zone of PTHrP production into that associated with the growth plate and that associated with the articular cartilage and joint (discussed later).[33] Within the growth plate, PTHrP is produced by immature, round chondrocytes at the top of the columns in response to another molecule known as *Indian Hedgehog* (*IHH*) that is produced by differentiating hypertrophic chondrocytes.[31] PTHrP, in turn, activates the PTH1R located on proliferating and prehypertrophic cells to maintain their proliferation and to slow their rate of differentiation into hypertrophic cells.[31] PTH1R expression is low in the round and proliferating chondrocytes but is upregulated within prehypertrophic chondrocytes. This system describes a local negative feedback loop that allows IHH and PTHrP to act together to regulate the orderly differentiation and hypertrophy of the chondrocyte columns and the elongation of the developing bones.[31] Genetic experiments in mice have demonstrated that loss of either PTHrP or the PTH1R leads to a foreshortening of the bones due to premature differentiation of the growth plate chondrocytes and loss of their proliferative capacity.[31,33] Interestingly, overexpression of PTHrP in chondrocytes also results in short bones, but this is caused by a severe impairment in chondrocyte differentiation and a disruption of the orderly architecture of the growth plate.[31] Loss of PTH1R function in human fetuses with Blomstrand's chondrodysplasia also impairs bone growth and mimics the phenotype of PTHrP- and PTH1R null mice.[34]

KEY POINTS

- Local parathyroid hormone-related protein controls the proliferation and differentiation of chondrocytes in the developing growth plate.

In recent years, many details about the network of signals though which PTHrP exerts it effects on chondrocyte differentiation have emerged. IHH increases PTHrP expression at the ends of the growth plate primarily through direct effects, but it may also act indirectly through TGF-β signaling.[31] IHH upregulates PTHrP expression in the growth plate by antagonizing the activity of the transcription factor Gli3.[31] PTHrP acts on chondrocytes through the PTH1R primarily by stimulating cAMP production and PKA activity, which, in turn, mediate a series of downstream events including phosphorylation of SIK3 and SOX9; inhibition of p57 expression; induction of Gli3, Bcl-2, and cyclin D1 expression; and, eventually, the phosphorylation and degradation of Runx2 and Runx3, two transcription factors necessary for chondrocyte differentiation.[31,35] It has also been demonstrated that PTHrP modulates chondrocyte differentiation by inducing the phosphorylation and inactivation of SIK3 kinase, which promotes the translocation of HDAC4 and HDAC5 into the nucleus. Once in the nucleus, HDAC4 and HDAC5 negatively regulate the activity of a network of transcription factors, including Zfp521, MEF2, and Runx2.[11,35,36] Multiple mouse genetic models have confirmed that this pathway is required for PTHrP's actions. As previously mentioned, PTHrP knockout mice die perinatally of accelerated chondrocyte hypertrophy, but simultaneous deletion of SIK3 in proliferating chondrocytes completely abrogated this phenotype.[35] Mice engineered to disrupt both HDAC4 and HDAC5 die at birth, with a phenotype similar to that of PTH1R knockout mice.[36] Finally, the lack of Zfp521 rescues the abnormal growth plate phenotype in mice that overexpress a constitutively active PTH1R.[35,37] In humans, mutations in the *PTHRP* and *HDAC4* genes cause a form of chondrodysplasia known as *brachydactyly* type E, which mimics skeletal abnormalities found in patients with mutations in the *GNAS* gene, suggesting that these genes are in the same genetic pathway in both mice and humans.[38] In summary, PTHrP signaling regulates a complex web of downstream events that affect chondrocyte proliferation and differentiation to ensure orderly bone growth during development.

There is a population of chondrocytes within the resting zone, located at the top of the growth plate, that persistently express PTHrP after fetal life.[33] Lineage tracing experiments showed that these PTHrP-positive resting-zone chondrocytes contributed to the pool of columnar chondrocytes but also became osteoblasts and marrow stromal cells beneath the growth plate, suggesting that they served as stem/progenitor cells for bone growth.[33] Importantly, whole-body ablation of the PTHrP-expressing cells or disruption of the *Pthlh* gene in chondrocytes after birth caused abnormal chondrocyte differentiation and premature loss of the growth plate.[33,39] These studies documented that PTHrP also regulates chondrocyte differentiation and maintenance in the mature growth plate, and raised the intriguing possibility that loss of PTHrP signaling may contribute to growth plate closure during the adolescent growth spurt, especially because IGF1 regulates PTHrP production by growth-plate chondrocytes.[40]

PTHrP is produced in other cartilaginous sites, such as the perichondrium that surrounds the costal cartilage and nasal cartilage, as well as by the subarticular chondrocyte population immediately subjacent to the hyaline cartilage lining the joint space.[11] These are sites of permanent cartilage, and the cells in these structures do not undergo differentiation, hypertrophy, and mineralization as in the growth plate. In these sites, it appears that PTHrP inhibits hypertrophic differentiation of chondrocytes and prevents the inappropriate encroachment of bone into these structures.[11] PTHrP is often regulated by mechanical forces and, interestingly, its expression within the articular cartilage of joints is load-dependent.[41] Deletion of PTHrP in these cells and/or unloading of the joints leads to abnormal mineralization of cells just under the articular surface, suggesting that PTHrP may normally maintain the undifferentiated state of articular chondrocytes and help prevent osteoarthritis.[11]

PTHrP is prominently expressed at the insertion sites of ligaments and tendons into bone, called *entheses*.[42] Specifically, it is expressed in the fibrous layer of the periosteum and in fibrous entheses that attach tendons and ligaments to the cortical bone surface. At these sites, PTHrP is induced by mechanical loading and upregulates RANKL production to induce osteoclast formation.[43] In the periosteum, these osteoclasts are uncoupled from osteoblast formation and serve to model the periosteal surface during growth and development. In the fibrous entheses, these osteoclasts erode the cortical surface to create the root system by which the tendons and ligaments are anchored to cortical bone. In general, this osteoclastic resorption is subsequently coupled to osteoblastic bone formation that anchors the insertion in place, but in certain sites, such as the tibial insertion of the medial collateral ligament, the resorption is uncoupled, which permits the insertion site to migrate to accommodate linear growth and thereby maintain its biomechanical function as a collateral ligament.[43]

A final function of PTHrP in the skeleton is the regulation of osteoblast and osteocyte anabolic function. There is some disagreement over the PTHrP-expressing population(s) of osteoblasts in the skeleton. Many studies in cultured osteoblasts demonstrate that these cells produce PTHrP and express the PTH1R providing the possibility for paracrine and/or autocrine regulation of osteoblast function.[44,45] Furthermore, there is extensive literature demonstrating that activation of the PTH1R in osteoblasts induces proliferation of osteoblasts and production of osteoclast-inducing cytokines, such as CSF-1 and RANKL, and inhibits full differentiation of osteoblasts (see Chapters 47 and 51).[44,45] However, studies using a PTHrP-lacZ knockin reporter mouse suggested that typical osteoblasts on trabecular and endosteal surfaces did not express PTHrP.[11] Nevertheless, genetic manipulation of the *PTHRP* gene in osteoblasts *in vivo* causes profound changes in bone homeostasis. First, it was shown that, while heterozygous PTHrP-null mice are normal at birth, they develop progressive osteopenia with age.[46] In addition, selective deletion of the *Pthlh* gene from osteoblasts caused decreased bone mass, reduced bone formation, and a reduction in the formation and survival of osteoblasts.[47] While osteoblasts clearly express the PTH1R studies in cultured cells have suggested that PTHrP can also affect osteoblast biology via a nuclear pathway. Loss of the nuclear PTHrP pathway in PTHrP 1–84 knockin or PTHrP 1–66 knockin mice causes defects in osteoblast proliferation and function and is associated with low bone mass.[28] Thus, manipulation of the *Pthlh* gene *in vivo* affects the behavior of osteoblasts and alters bone mass. However, it is not entirely clear whether PTHrP affects osteoblasts in an autocrine or intracrine fashion, or whether it is produced by other cell types, such as osteocytes, and acts on osteoblasts in a paracrine fashion.

Recent studies have disrupted either the *Pthlh* or the *Pth1r* genes in osteocytes in mice. Loss of osteocyte PTHrP production reduced bone mass, which was associated with low osteoblast numbers and mineralizing surfaces. Moreover, *in vitro* experiments in cultured osteocytes showed that they secrete full-length PTHrP, which, in turn, regulated the expression of genes involved in matrix mineralization through autocrine and/or paracrine activation of the osteocyte PTH1R (Fig. 48.6).[14] Consistent with these findings, ablation of the PTH1R in osteocytes has profound effects on the activity of surface osteoclasts and osteoblasts *in vivo,* although these results are likely a composite of loss of PTHrP signaling from osteocytes and osteoblasts, as well PTH signaling from the circulation.[48,49] Collectively, these studies suggest that osteocytes can stimulate bone formation by secreting PTHrP, which may act in an autocrine/paracrine manner to promote bone formation. What triggers PTHrP expression in osteocytes in the first place and whether PTHrP can be transported through the lacunocanalicular network remain unknown. Further research is needed to answer these questions. Nevertheless, the ability of local PTHrP to stimulate bone formation is exploited in the clinic for the treatment of osteoporosis. Abaloparatide, a US Food and Drug Administration (FDA)-approved synthetic PTHrP analog, as well as teriparatide, an FDA-approved fragment of PTH, both exert potent anabolic activity that increases bone formation and bone mass and are used to treat patients with osteoporosis. Both of these drugs mimic pathways that likely reflect the local functions of PTHrP on bone formation (see “Skeletal Diseases”).

The Mammary Gland

Soon after its discovery, PTHrP was reported to be expressed in mammary tissue and to be secreted in milk.[50] Subsequently, PTHrP was shown to be critically important for the development and functioning of the breast throughout life. PTHrP serves distinct functions during different stages of mammary development; we will first discuss PTHrP’s functions during embryonic breast development and then its functions during lactation.

In mice, embryonic mammary development begins with the formation of 10 mammary buds, each of which consists of a bulb-shaped collection of epithelial cells surrounded by several layers of specialized fibroblasts known as the *mammary mesenchyme.*[51] Once formed, the mammary buds remain quiescent until embryonic day 16, when they give rise to a mammary sprout that develops into the rudimentary ductal tree. At the time of birth, the gland consists of a simple epithelial ductal tree consisting of 15 to 20 branched tubes within a fatty stroma.[51] This initial pattern persists until puberty, at which time the mature virgin gland is formed through a second round of branching morphogenesis that is regulated by circulating hormones.

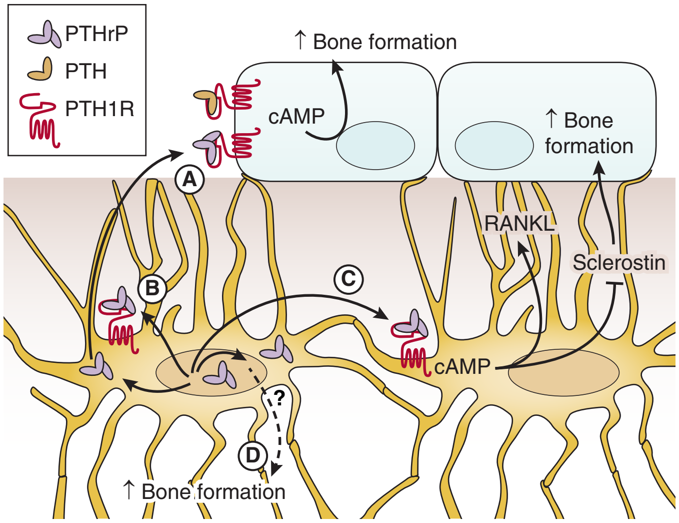

Fig. 48.6 Osteocytes can stimulate bone formation by secreting parathyroid hormone-related protein (PTHrP). (**A**), Full-length PTHrP produced and secreted by osteocytes promotes bone formation by activating the type 1 parathyroid hormone/parathyroid hormone-related protein receptor (PTHR1) from osteoblasts and their precursors, but also by acting in an autocrine (**B**) and paracrine (**C**) manner in osteocytes to regulate gene expression, including suppressing sclerostin production, which promotes bone formation by osteoblasts and stimulating RANKL production. (**D**), In addition, PTHrP promotes bone formation through its receptor-independent intracrine actions by mechanisms that are yet to be elucidated. PTH, Parathyroid hormone; cAMP, cyclic adenosine monophosphate. (Reproduced from Kronenberg HM. PTHrP and skeletal development. *Ann N Y Acad Sci*. 2006;1068:1–13.)

PTHrP is expressed in the nascent mammary gland, within epithelial cells coalescing into the developing mammary buds (Fig. 48.7).[52] The *Pthlh* gene continues to be expressed in all epithelial cells of the embryonic duct system,[51,52] but, after birth, *Pthlh* gene expression becomes restricted principally to myoepithelial cells.[52] In contrast to the *Pthlh* gene, the *Pth1r* gene is expressed within the mammary mesenchyme, but its expression is more widespread throughout the developing dermis.[51] It is not clear when the PTH1R is first expressed within the subepidermal mesenchyme. However, PTH1Rs are already present when the mammary bud begins to form, and the receptor continues to be expressed throughout embryonic development.[51] Similar patterns of epithelial PTHrP expression and mesenchymal PTH1R expression have been documented in the embryonic breast buds of human fetuses.[53,54]

Studies in genetically altered mouse models have demonstrated that PTHrP signaling is required for the differentiation of the specialized mammary mesenchyme and for the development of the embryonic duct system. As the mammary bud invaginates into the mesenchyme, PTHrP, produced by mammary epithelial cells, interacts with the PTH1R on the immature mesenchymal cells closest to the epithelial bud and triggers these cells to differentiate into mammary mesenchyme. PTHrP accomplishes this, in part, by facilitating local activation of Wnt and BMP signaling specifically within mesenchymal cells.[55] Although mammary buds form normally in PTHrP$^{-/-}$ and PTH1R$^{-/-}$ embryos, the lack of mammary mesenchyme leads to the subsequent failure of further mammary ductal development.[51] In the absence of PTHrP or the PTH1R the mammary buds never give rise to the neonatal mammary ducts, and these mice lack mammary epithelial structures. In addition, PTHrP$^{-/-}$ and PTH1R$^{-/-}$ mice lack nipples, because the mammary mesenchyme is also required to direct the epidermis to form these structures coincident with the outgrowth of the mammary ducts. Similarly, PTHrP is important for human fetal breast development. Blomstrand's chondrodysplasia is a fatal form of dwarfism caused by null mutations of the PTH1R gene,[34] and affected fetuses lack breast ducts and nipples.[54]

PTHrP also contributes to mammary physiology during lactation. *Pthlh* gene expression is upregulated in alveolar epithelial cells at the start of lactation under the control of both local and systemic factors.[56] Thiede and Rodan originally reported that PTHrP expression in rats depends on suckling and on serum prolactin concentrations.[57] However, prolactin most likely serves as a permissive factor, as additional studies have shown that the suckling response is a local one, and that PTHrP expression only rises in the milked gland.[56] Much of the PTHrP made during lactation ends up in milk, in which levels of PTHrP are up to 10,000-fold higher than in the circulation of normal individuals and 1000-fold higher than in patients suffering from humoral hypercalcemia of malignancy.[11] PTHrP concentrations in milk have generally been found to mirror RNA levels in the gland, increasing over the duration of lactation and rising acutely with suckling.[11] In addition, evidence shows that milk PTHrP levels may vary with the calcium content of milk.[58] In mice, the CaSR on the basolateral surface of mammary epithelial cells regulates PTHrP production, such that increased delivery of calcium to the mammary gland decreases PTHrP production and secretion into milk.[59]

Milk production requires a great deal of calcium, and the maternal skeleton serves as an important source of the calcium transported into milk.[58] Overall rates of bone turnover are elevated during lactation, but bone resorption outstrips bone formation so that bone mass declines rapidly. Nursing women lose between 5% and 10% of their bone mass over 6 months, while rodents lose up to one third of their skeletal mass over 21 days of lactation.[56,58] In mice, bone resorption is increased in great part due to the combination of decreased systemic estradiol concentrations and elevated circulating PTHrP levels.[58] Many studies have now documented elevated circulating PTHrP levels in lactating humans and rodents, and PTHrP levels correlate directly with biochemical markers of bone resorption and inversely with bone mass in lactating mice.[58,60] In addition, circulating PTHrP levels have been shown to correlate with bone density changes in lactating humans.[61] When the *Pthlh* gene was disrupted specifically in the lactating mammary gland in mice, circulating PTHrP levels declined, milk PTHrP became unmeasurable, rates of bone resorption decreased, and bone loss was reduced by 50%.[62] These data demonstrate that the lactating mammary gland secretes PTHrP both into milk and to the circulation, where it acts together with estrogen deficiency to stimulate bone resorption and cause bone loss. As noted previously, the production of PTHrP by the lactating breast is decreased by stimulation of the CaSR on mammary epithelial cells.[59] Therefore, as shown in Fig. 48.8, a classic endocrine negative feedback loop is created between bone and breast during lactation. If calcium delivery to the gland falls, mammary epithelial cells produce more PTHrP, which stimulates increased bone resorption. The delivery of more calcium to the mammary gland from the skeleton then stimulates the CaSR and decreases PTHrP production.

KEY POINTS

- Mammary gland–derived parathyroid hormone-related protein contributes to the regulation of calcium and bone metabolism during lactation.

The exact function of PTHrP in milk remains unclear. Genetic removal of PTHrP from the mammary gland does not alter milk calcium levels, and PTHrP-null mammary epithelial cells are able to transport calcium *in vitro* at the same rate as wild-type mammary

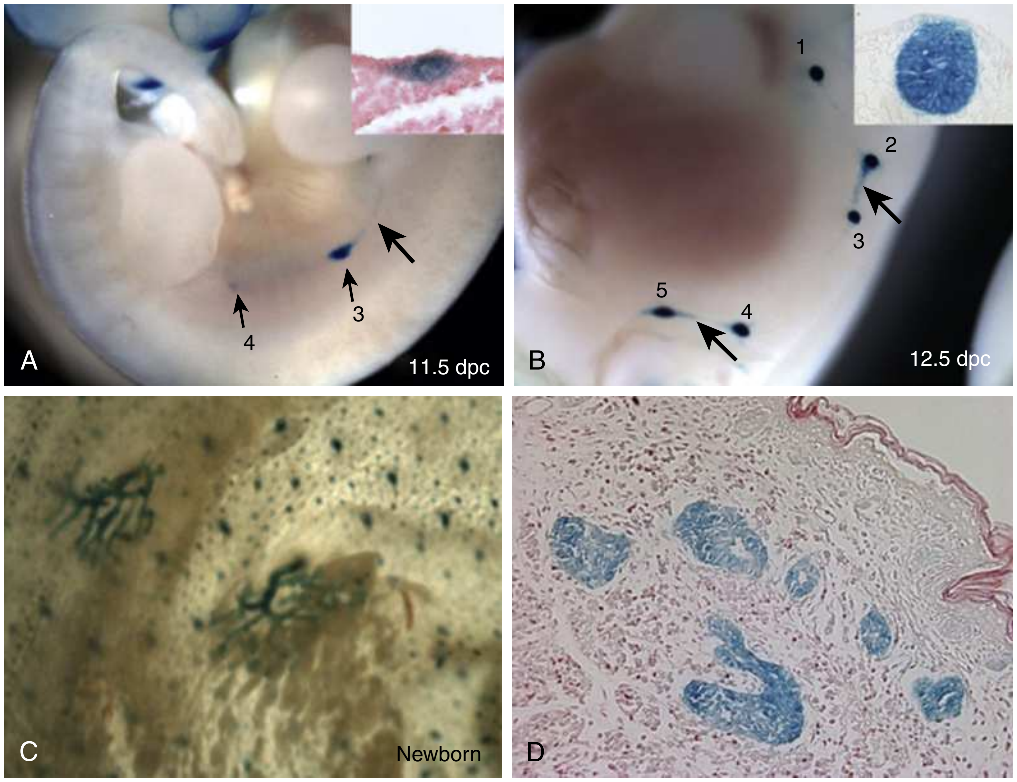

Fig. 48.7 Parathyroid hormone-related protein (PTHrP) is expressed in embryonic mammary glands and skin as indicated in PTHrP-lacZ knockin mice. A, At embryonic day (E) 11.5, PTHrP is expressed *(blue staining)* within the mammary line *(large arrow)* and in the forming mammary placodes *(arrows).* Inset shows section through mammary placode. **B,** By E12.5, PTHrP is expressed within the mammary buds *(inset)* and within cells migrating toward the forming buds *(double arrows).* **C,** At birth, PTHrP is expressed within the branching ductal tree of the neonatal mammary gland but also within the forming hair follicles in the skin *(punctate pattern).* **D,** Sections through the newborn skin show PTHrP expression within the epithelial cells of the mammary ducts. *dpc,* Days postconception. (Reproduced from Boras-Granic K, VanHouten J, Hiremath M, et al. Parathyroid hormone-related protein is not required for normal ductal or alveolar development in the post-natal mammary gland. *PLoS One.* 2011;6:e27278.)

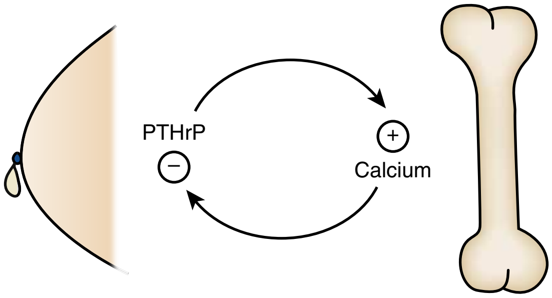

Fig. 48.8 The breast and the skeleton communicate during lactation in order to provide a steady supply of calcium for milk production. The lactating breast secretes parathyroid hormone-related protein (PTHrP) into the systemic circulation during lactation. PTHrP interacts with the type 1 parathyroid hormone/parathyroid hormone-related protein receptor in bone cells in order to increase the rate of bone resorption and liberate skeletal calcium stores. Mammary epithelial cells in the lactating breast express the calcium-sensing receptor and suppress PTHrP production in response to increased delivery of calcium, defining a classical endocrine negative feedback loop between breast and bone.

epithelial cells.[62] However, there is a dose-responsive, inverse relationship between milk PTHrP levels and neonatal ash calcium content in mice.[63] The mechanism(s) by which milk PTHrP modulates neonatal calcium and/or bone metabolism remains unexplored. Nevertheless, given that PTHrP levels vary inversely with maternal calcium availability and milk calcium content, these observations suggest that PTHrP may act as a "metabolic messenger" in milk to adjust neonatal bone and mineral metabolism to the mother's ability to supply calcium in milk.

The Skin

Normal human keratinocytes were the first nonmalignant cells demonstrated to produce PTHrP.[64] Subsequently, multiple studies have confirmed that cultured rodent and human keratinocytes secrete bioactive PTHrP (reviewed in[2]). The *Pthlh* gene is expressed most prominently within hair follicles, both during development and in the adult, where mRNA levels have been shown to vary with the hair cycle.[65] Low levels of *Pthlh* expression may also be found throughout the interfollicular epidermis. The PTH1R is expressed on dermal fibroblasts, and PTHrP has been shown to bind to skin fibroblasts and to elicit a variety of biological responses.[11] In addition to fibroblasts, studies using sensitive PCR-based detection methods have also reported expression of *Pth1r* mRNA in keratinocytes, although these studies used cultured cells.[66]

Several studies suggest that PTHrP participates in the regulation of the hair cycle. During development, disruption of the *Pthlh* or *Pth1r* genes does not seem to affect initial hair follicle morphogenesis or patterning in mice, except for the vicinity of the nipple.[11] However, in mature mice, systemic or topical administration of PTH1R antagonists perturbs the hair cycle by prematurely terminating telogen, prolonging anagen growth, and inhibiting catagen.[67] In a reciprocal fashion, mice overexpressing PTHrP in basal keratinocytes demonstrate a delayed emergence of dorsal hair and have shorter hairs, and their hair follicles enter catagen approximately 2 days early.[68] These findings were associated with a lower proliferation rate in the hair matrix and a less well-developed perifollicular vasculature during anagen. Together, these studies imply that PTHrP may regulate the anagen to catagen transition, acting to inhibit hair follicle growth by pushing growing hair follicles into the growth-arrested or catagen/telogen phase of the hair cycle. If this hypothesis were correct, one would expect PTHrP knockout mice to exhibit findings similar to PTH1R antagonist–treated mice. However, this does not appear to be the case. In mice that lack PTHrP in their skin, the hair cycle appears to be normal.[69] In fact, rather than a promotion of hair growth, these mice demonstrate a thinning of their coat over time. These conflicting results are difficult to reconcile, but suggest that, while PTHrP may contribute to the regulation of the hair cycle, it is unlikely to be necessary for this process to unfold normally.

PTHrP has also been implicated in the regulation of keratinocyte proliferation and/or differentiation. A careful comparison of the histology of PTHrP-null and PTHrP-overexpressing skin demonstrated reciprocal changes. In the absence of PTHrP, keratinocyte differentiation was accelerated, whereas in skin exposed to PTHrP overexpression, keratinocyte differentiation was delayed.[69] Therefore, in a physiologic context, PTHrP appears to slow the rate of keratinocyte differentiation and to preserve the proliferative basal compartment, effects that are analogous to those noted for chondrocyte differentiation in the growth plates of mice overexpressing PTHrP as compared with PTHrP- and PTH1R-null mice.[11]

Recent experiments have suggested that nuclear and/or C-terminal PTHrP may function to protect skin from aging. Knockin PTHrP 1–84 mice have a thinner epidermis and decreased subcutaneous fat and collagen bundles that suggest premature ageing. This is associated with decreased skin cell proliferation, increased apoptosis, and inappropriate senescence due to the upregulation of p27 and other CDK inhibitors. These findings suggest that the NLS and C-terminus of PTHrP are important to skin homoeostasis and raise the interesting possibility that decreased PTHrP expression could contribute to aging *in vivo*.[29]

Finally, it has been suggested that PTHrP contributes to innate immunity in the epidermis that protects against bacterial invasion. Muehleisen and colleagues reported that PTHrP signaling through the PTH1R in keratinocytes interacted synergistically with vitamin D to induce cathelicidin production and protect against experimental skin infection with group A *Streptococcus.*[70] The authors showed that PTH1R receptor expression was induced in keratinocytes by 1,25-vitamin D signaling. Furthermore, they showed that PTHrP expression was induced in keratinocytes by exposure to the bacterial product and TLR2 agonist lipoteichoic acid. These results suggest that local production of PTHrP in response to TLR activation serves to trigger the production of antimicrobial peptides, and that vitamin D may enhance the sensitivity of this regulatory loop by upregulating PTH1R expression. These are intriguing findings, and we will discuss other potential roles of PTHrP-PTH1R signaling in immunity later (see “The Immune System”).

Placenta

PTHLH mRNA and PTHrP protein have been detected in rat and human placenta in both cytotrophoblasts and syncytiotrophoblasts, as well as in mouse trophoblast giant cells.[11] The cuboidal cells of the amniotic membranes also express PTHrP, and these cells are likely the source of the PTHrP found in amniotic fluid.[71] PTHrP has effects on early trophoblast differentiation and is an important regulator of murine placental development, but the best-studied aspect of PTHrP in the placenta is its involvement in calcium transport.[72] Almost all of the calcium required for mineralization of the fetal skeleton is transferred from the mother to the fetus across the placenta during a relatively short interval in late pregnancy.[58] Both total and ionized calcium concentrations are higher in the fetal circulation than they are in the maternal circulation, demonstrating that calcium is actively transported across the placenta against an uphill concentration gradient. In mice homozygous for deletion of the *Pthrp* gene, fetal plasma calcium and the maternal-fetal calcium gradient are significantly reduced. When fetuses were injected *in utero* with fragments of PTHrP or PTH, calcium transport from the mother into the fetus was significantly restored only by treatment with a midmolecule PTHrP peptide that cannot stimulate the PTH1R.[58] The circulating PTHrP in fetal mice is thought to be derived from liver and placenta.[58] Other studies have demonstrated that PTH also contributes to the regulation of placental mineral transport and fetal mineral metabolism.[58] PTH appears to operate mainly on the fetal skeleton and kidneys to prevent fetal hypocalcemia, while PTHrP acts to stimulate transplacental calcium transport and raises the fetal calcium level above that in the maternal circulation, resulting in the typical suppression of PTH in the fetal circulation.

Endocrine Pancreas

Soon after its discovery, PTHrP expression was detected in all four cell types of pancreatic islets (α, β, δ, and pancreatic polypeptide cells).[73] More recent studies have verified that PTHrP is produced by rodent islet cells and human islet cells in primary tissue culture.[11] Islet cells also express the PTH1R and studies suggest that most of the observed biological actions of PTHrP in the endocrine pancreas are mediated by signaling from the PTH1R.[74]

PTHrP stimulates the proliferation of mouse and human pancreatic β cells during development and in the adult pancreas.[74] Vasavada and coworkers generated transgenic mice that overexpress PTHrP under the control of the rat insulin-II promoter (RIP).[75,76] RIP-PTHrP mice display striking degrees of islet hyperplasia and an increase in islet numbers compared with their control littermates (Fig. 48.9). This increased islet cell mass is the result of increased proliferation and decreased apoptosis, and it is associated with hyperinsulinemia and hypoglycemia, as well as resistance to the diabetogenic effects of the β cell toxin streptozotocin.[75,76] The effects of PTHrP on β cell proliferation have been further studied in rodent and human islet cells *in vitro.*[74] Proliferation is induced by N-terminal portions of PTHrP and depends on activation of the PTH1R, as well as downstream signaling via activation of PKC-ζ, cyclin E, and cdk2.[77,78] Furthermore, acute treatment with N-terminal PTHrP improved glucose-stimulated insulin secretion both in cultured β cells and in intact mice.[74,77,78] Increases in insulin expression and secretion in cultured rodent islet cells appear to be mediated by alterations in MAPK-associated phosphatase activity and inhibition of c-Jun N-terminal kinase.[79] Remarkably, daily subcutaneous injections of PTHrP 1–36 in normal adult mice or in a model of β cell deficiency increased the proliferation of β cells in islets *in vivo* and improved glucose tolerance, suggesting that PTHrP administration may prove useful in the maintenance and regeneration of islet cell mass for the treatment of diabetes.[78,80]

KEY POINTS

- Parathyroid hormone-related protein can regulate pancreatic β cell mass and may be useful in the treatment of diabetes.

Smooth Muscle and the Cardiovascular System

PTHrP is produced by smooth muscle cells in response to mechanical deformation and functions in a short feedback manner to relax the

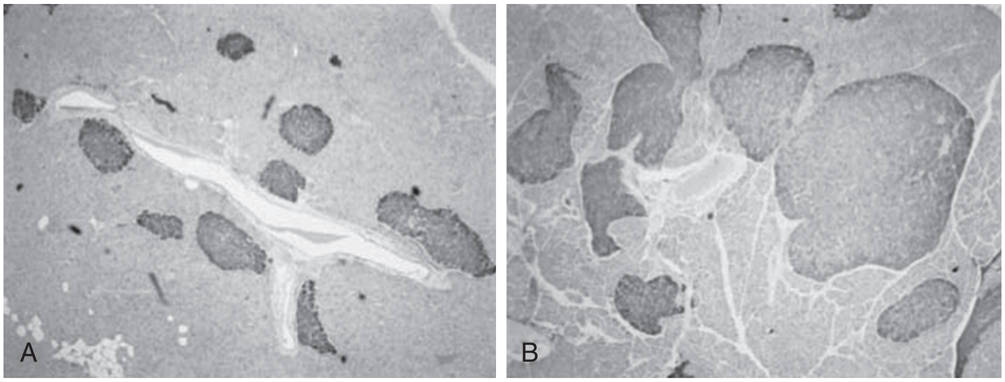

Fig. 48.9 **Overexpression of parathyroid hormone-related protein (PTHrP) in pancreatic islets causes islet hyperplasia.** Immunohistochemistry for insulin *(dark staining)* in normal mouse pancreas (**A**) and in RIP-PTHrP transgenic pancreas (**B**). Note that overexpression of PTHrP in β cells leads to an obvious increase in the number and size of pancreatic islets. (Reproduced from Porter SE, Sorenson RL, Dann P, et al. Progressive pancreatic islet hyperplasia in the islet-targeted, parathyroid hormone-related protein-overexpressing mouse. *Endocrinology*. 1998;139:3743–3751.)

stretched muscle.[1,2,11] This was initially studied in the uterus, where it was shown that PTHrP expression is induced by distension of the uterine horn by the developing fetus or by experimentally stretching the uterus.[81] In turn, treatment of rat, baboon, and human myometrium with PTHrP *ex vivo* results in reductions in isometric tension and inhibits spontaneous and electrically-induced contractions.[11] In baboon myometrium, PTHrP can counter the effects of oxytocin to induce uterine contraction.[82] These observations suggested that PTHrP may cause gradual relaxation of the uterus to accommodate the growth of the fetal-placental unit and/or to inhibit premature labor. Interestingly, the effects of PTHrP on myometrial contractivity wane with progression of pregnancy in rats, and the uterus becomes resistant to PTHrP after labor has been initiated.[11]

PTHrP was also shown to be expressed in both fetal and adult heart tissue from rats and humans, where it was suggested to have cardioprotective effects.[83] Infusions of PTHrP 1–34 improved the contractility of the rat and pig myocardium after stunning.[84] In primary cultures of endothelial cells and cardiomyocytes, PTHrP inhibited apoptosis.[85] Finally, the administration of PTHrP 87–139 enhanced cardiac angiogenesis and inhibited myocardial apoptosis and fibrosis after experimental myocardial infarction.[86] Although more research is needed to understand the role of PTHrP in normal and injured heart tissue, these results suggest that PTHrP may be cardioprotective and could be used therapeutically to preserve cardiac function in patients with myocardial ischemia or infarction.

PTHrP is induced by vasoconstrictive agents as well as stretch itself, and acts as a vasodilator in resistance blood vessels.[87] As a result, PTHrP may act to modulate local blood flow in a variety of tissues.[88] PTHrP has also been shown to regulate the proliferation of vascular smooth muscle cells. Secreted N-terminal PTHrP inhibits the proliferation of vascular smooth muscle cells by acting via the PTH1R on the cell surface. However, the midregion and C-terminal portions of PTHrP act in the nucleus to stimulate the proliferation of these cells *in vitro* and *in vivo* by inducing the expression of c-myc and skp2, which, in turn, reduce levels of the cell-cycle inhibitor p27, promoting progression through the G_1/S checkpoint.[26] This pathway appears to be active during development, because the rate of proliferation of smooth muscle cells in the aorta of PTHrP$^{-/-}$ embryos is reduced.[89] Furthermore, PTHrP expression is upregulated by vascular damage following balloon angioplasty and in atherosclerotic lesions in rodents and in humans. Several studies have suggested that PTHrP plays an important role in the response of these cells to injury and may contribute to the pathophysiologic development of a neointima following angioplasty.[90]

Teeth

Developing teeth become surrounded by alveolar bone but must maintain a bone-free cavity or crypt to allow for their morphogenesis. After teeth are formed, they must then erupt through the roof of the dental crypt in order to emerge into the oral cavity. The process of tooth eruption relies on geographically uncoupled bone turnover, in which osteoclasts form over the crown of the tooth in order to resorb the overlying bone, and osteoblasts at the base of the tooth propel it upward out of the crypt. PTHrP/PTH1R signaling is a key regulator of this process, because loss-of-function mutations of the PTH1R lead to a failure of tooth eruption in humans.[91,92] In mice, disruption of the *Pthlh* gene causes the same phenotype: teeth develop, but they do not erupt. PTHrP is normally produced by stellate reticulum cells and signals to dental follicle cells in order to drive the formation of osteoclasts above the crypt. In the absence of PTHrP, these osteoclasts do not appear, eruption fails to occur, and teeth become impacted.[93] In addition to being critical for tooth eruption, PTHrP/PTH1R signaling in dental mesenchymal progenitors has been shown to be essential for tooth root formation in mice. However, it is unclear whether this is also true in humans.[94]

The Nervous System

PTHrP and PTH1R are expressed in both the central nervous system (CNS) and peripheral nervous system. In the rat brain, PTHrP was found to be expressed mainly in the cerebral cortex, hippocampus, and cerebellum, whereas PTH1R is more widely distributed.[95] Interestingly, PTHrP is also found in human cerebrospinal fluid in levels that are at least 50 times those found in serum, and its abundance positively correlates with increased age.[96] At present, the exact role of PTHrP in the CNS remains unclear. Primary cultures of various neuronal and glial cell populations respond to exogenous PTHrP.[97-99] Furthermore, experiments in PTHrP knockout mice rescued from neonatal death by transgenic expression of PTHrP targeted to chondrocytes showed that lack of PTHrP was not associated with anatomical defects in the brain. However, primary cultures of cerebral cortical cells lacking the *Pthlh* gene showed increased susceptibility to excitotoxic agents, suggesting that PTHrP may have a neuroprotective function in the brain.[97] In contrast, PTHrP 1–84 knockin mice display abnormal brain development associated with decreased proliferation and increased apoptosis in neuronal cells that affects hippocampal synaptic transmission and plasticity, suggesting that the NLS and/or C-terminus of PTHrP may be important for normal brain development and function.[100]

The Immune System

The thymus is one of the primary lymphoid organs of the immune system in which T-cell development takes place. PTHrP and PTH1R have been shown to be expressed in thymic epithelial cells (TECs) from both human and mouse thymus. Treatment of primary cultures of human TECs with PTHrP stimulates the production of IL-6, which is important for the maturation and development of thymocytes. Moreover, PTHrP 1–84 knockin mice display abnormal development of T-cells, indicating that the NLS and C-terminus of PTHrP may be necessary for the normal formation of this cell type.[101-103]

Several *in vitro* and *in vivo* experiments have shown that PTHrP can trigger and mediate the inflammatory response in different tissues in disorders like pancreatitis, nephritis, atherosclerosis, and brain injury, among others.[104-108] Interestingly, PTHrP 107–111 was recently shown to have the opposite effect, improving arthritis by inhibiting immune activation, proinflammatory cytokines, osteoblast senescence, and osteoclastogenesis, indicating that it could modulate aspects of the pathophysiology of osteoarthritis.[109,110]

PARATHYROID HORMONE-RELATED PROTEIN IN DISEASE

Given the diverse biological effects of PTHrP, one might expect that it is involved in the pathogenesis of diseases. The most established role for PTHrP in disease states is to cause hypercalcemia in patients with cancer. This occurs because PTHrP and PTH share the same receptor, but normally PTHrP does not circulate. However, in some tumors, PTHrP is made in sufficient quantities to reach the circulation and to stimulate PTH1R receptors in the bone and kidney normally meant to mediate the functions of PTH, thus mimicking many aspects of primary hyperparathyroidism. The topic of hypercalcemia in malignancy is covered in detail in Chapter 55. What follows here is a short discussion of other conditions in which PTHrP may play a pathophysiologic role or conditions in which it may have therapeutic applications.

Cancer

Many studies have suggested that PTHrP modulates the proliferation, differentiation, and/or survival of cancer cell lines from a variety of different tumor types *in vitro*.[2,11,111] However, there are many fewer studies that address the possibility that PTHrP contributes to tumor cell growth in animal models *in vivo* or in human cancers. These data do exist for breast cancer, although studies in cultured breast cancer cell lines, animal models, and clinical studies have yielded conflicting results.[112] Some case series suggest that PTHrP expression predicts a more aggressive clinical course.[112] However, other studies have suggested just the opposite. First, Henderson and colleagues examined 526 consecutive cases of breast cancer and found that PTHrP expression was an independent predictor of a more benign clinical course.[113] More recently, in two additional patient cohorts totaling nearly 800 patients, the authors found that PTHrP levels were downregulated in malignant epithelium, and that lower levels of nuclear-localized PTHrP in cancer cells correlated with unfavorable clinical outcomes.[114] In addition to these case studies, several large genome-wide association studies (GWAS) have implicated the *PTHLH* gene as a breast cancer susceptibility locus.[115] While GWAS do not provide mechanistic insight, they do underscore the fact that the effects of PTHrP in breast cancer are likely to be clinically important.

KEY POINTS

- Parathyroid hormone-related protein contributes to the development and/or progression of breast cancer.

Conflicting results have also been reported in studies employing transgenic models of breast cancer. Fleming and colleagues demonstrated that mammary-specific disruption of the *Pthlh* gene increased the incidence of tumors in MMTV-Neu mice.[116] In contrast, Li and colleagues used an identical genetic approach and found that disruption of the *Pthlh* gene dramatically prolonged tumor latency, slowed tumor growth, and reduced metastases caused by transgenic overexpression of the polyoma middle T antigen (MMTV-PyMT mice).[117] Moreover, using the same MMTV-PyMT mice breast cancer model, Kim et al. demonstrated that CaSR signaling stimulates the growth of mammary tumors, at least in part, by upregulating PTHrP production *in vitro* and *in vivo*. These findings were further supported by a positive correlation between CaSR and PTHrP mRNA expression in human samples.[118] The opposing results from these different transgenic mouse studies suggest that the molecular context of transformation may be critical for determining PTHrP's actions, and this may help explain the variability in the clinical observations.

Another function of PTHrP in breast cancer is its contribution to the osteolysis that is required for the formation of bone metastases.[119] In addition, although prostate cancer is often associated with osteoblastic bone metastases, studies in xenograft models of human prostate cancer cell lines have suggested that PTHrP also promotes the survival and growth of prostate cancer in the skeleton.[120] In breast cancers, experiments have suggested that, in response to the bone microenvironment, cells metastatic to the skeleton produce more PTHrP than cells in the primary tumor.[121] TGF-β, released at sites of bone resorption, has been shown to upregulate PTHrP production through a signaling pathway involving the transcription factor Gli2.[121] PTHrP, in turn, increases the production of RANKL and decreases the production of OPG, increasing osteoclast numbers and activity.[121] This sets up a feedforward loop between PTHrP production and bone resorption, contributing to a vicious cycle of osteolysis. However, there is conflicting clinical evidence as to whether PTHrP production by a primary breast tumor is predictive of bone metastases in patients.[121] One large and carefully controlled study suggested that PTHrP production by the primary tumor is actually a negative predictor, not a positive predictor, of skeletal metastases.[113] In contrast, a study of 125 patients with breast cancer and long-term clinical follow-up suggested that PTHrP staining in the primary tumor was predictive of bone metastases.[122] In agreement with this result, PTHrP expression examined in 497 cases of early breast cancer was found to be associated with bone metastasis and, in the estrogen receptor-negative subgroup, those who stained positive for PTHrP had a poor prognosis.[123] Furthermore, Washam and colleagues showed that the presence of PTHrP 12–48 in the circulation of human breast cancer patients was predictive of bone metastases.[124] This same group showed that PTHrP 12–48 could affect the differentiation of hematopoietic cells as well as the activity of osteoclasts, providing evidence that this peptide might somehow modulate tumor cell–bone cell interactions.[125]

Tumor-derived PTHrP can also alter energy metabolism and lead to a debilitating metabolic disorder termed cancer anorexia cachexia syndrome (CACS). CACS is caused by the tumor release of soluble factors leading to pronounced loss of weight, appetite, skeletal muscle, and fat mass. Several studies have implicated PTHrP in the pathogenesis of CACS. In a longitudinal observational cohort of 624 cancer patients, circulating PTHrP was found to be an independent predictor of weight loss.[126] Studies in mice carrying xenograft tumors producing

PTHrP suggested that it reduced food intake and promoted weight loss, which could be reversed by the administration of anti-PTHrP antiserum, resulting in prolonged survival.[121] More recently, Kir et al. suggested that PTHrP, produced by lung cancer cells, caused weight loss, fat wasting, and muscle atrophy, and suggested that this was due to adipocyte "browning" and a hypermetabolic state but not changes in appetite.[127] Again, treatment with anti-PTHrP antibodies prevented fat and muscle wasting in this model, and mice lacking PTH1R in adipocytes were resistant to cachexia driven by the same lung cancer xenograft tumor.[128] These studies implicate PTHrP as a contributor to CACS, and the fact that neutralizing antibodies can prevent the development of CACS in these mouse models suggests that targeting PTHrP-PTH1R signaling may be useful to treat cachexia.

Skeletal Disease

Given the extensive involvement of PTHrP in normal chondrocyte and bone biology, it is not surprising that alterations in PTHrP function are associated with skeletal diseases. The most obvious case is HHM, where circulating PTHrP interacts with PTH1R receptors in the skeleton to induce widespread bone resorption and produce hypercalcemia.[1] Loss-of-function mutations in the *PTHLH* gene cause Blomstrand's chondrodysplasia, which is associated with bone abnormalities that mimic the PTHrP knockout mouse and cause fetal demise.[34] Gain-of-function mutations in the *PTHLH* gene cause a rare disease termed Jansen's metaphyseal chondrodysplasia (JMC). This is a form of short-limbed dwarfism that results from inhibition of chondrocyte differentiation due to overactive PTH1R signaling.[34] Inverse agonist ligands that are able to suppress the basal cAMP signaling activity of the PTH1R are a promising therapy for JMC, a disorder that is currently without effective treatment.[129] As described previously, loss-of-function mutations in the *PTHLH* gene have been shown to cause brachydactyly type E, a syndrome including short stature, shortened metacarpals and metatarsals, and learning disabilities.[38] The functions of PTHrP in the maintenance of articular cartilage and modeling at ligamentous and tendinous insertion sites suggest that it may contribute to the pathophysiology of osteoarthritis or enthesopathies. Finally, the anabolic actions of PTHrP on bone have been the focus of multiple studies that evaluated its potential as a treatment for osteoporosis.[130] In 2017, the FDA approved an injectable synthetic analog of PTHrP for the treatment of postmenopausal women with osteoporosis at high risk of fracture. Abaloparatide is an N-terminal analog of PTHrP 1–34 that shares 76% homology with PTHrP 1–34 and 41% homology with PTH 1–34. The first 21 amino acids of abaloparatide are identical to PTHrP, but multiple substitutions have been made between amino acids 22 to 34 that conferred more stability. In pivotal trials, abaloparatide has been shown to be effective in reducing both vertebral and nonvertebral fractures and appears to provide a more rapid increase in bone mineral density than teriparatide (PTH 1–34).[131]

KEY POINTS

- A synthetic parathyroid hormone-related protein analog was approved for the treatment of postmenopausal women with osteoporosis.

Skin Disease

It has been suggested that defects in the skin and skin appendages in the rescued PTHrP-null mice are reminiscent of a series of disorders collectively known as the *ectodermal dysplasias*,[132] but the *PTHLH* gene has not been formally linked to any of these diseases. It has also been noted that psoriatic skin may downregulate PTHrP expression, and a small trial of topically-administered PTH suggested that stimulation of the PTH1R may improve the histologic abnormalities in psoriatic plaques.[133] However, these potentially exciting results have not yet been confirmed in larger trials. Preliminary studies also suggest that topical application of PTH1R antagonists may be useful for stimulating hair growth.[67] These original observations date back many years, but no further evidence has emerged to demonstrate whether manipulation of PTHrP-PTH1R signaling is an effective treatment for alopecia. Furthermore, a more recent study suggested that, in the setting of chemotherapy-induced alopecia, PTH1R agonists, but not an antagonist, stimulated hair regrowth.[134] Therefore, despite some intriguing preliminary findings, it is not entirely clear yet whether PTHrP is involved in skin pathology.

Diabetes

There is no evidence that PTHrP is involved in the pathogenesis of diabetes. However, because PTHrP induces proliferation and improves glucose-stimulated insulin secretion in human β cells, it is possible that it may be useful for the treatment of diabetes, especially in the setting of islet cell transplantation.[74] In support of these ideas, daily subcutaneous injections of PTHrP 1–36 have been shown to increase the proliferation of β cells in mouse islets *in vivo* and improve glucose tolerance in intact mice, as well as in a mouse model of β cell deficiency.[78,80] Interestingly, the same therapeutic approach was shown to be effective in restoring bone mass and strength in diabetic mice.[135] Patients with diabetes mellitus have alterations in bone structure and strength that compromise bone quality, increasing the risk for osteoporotic fractures.[136] Therefore, these results suggest that PTHrP treatment could be a useful therapeutic strategy to induce β cell proliferation and prevent bone fractures in diabetic patients.

CONCLUSION

The identification of PTHrP as the primary cause of HHM was the culmination of efforts from several investigators and the combination of basic and clinical research studies that elucidated the pathophysiology of this syndrome. Since then, we have learned much about the normal functions of PTHrP in well-studied sites such as bone, cartilage, pancreas, and breast. However, PTHrP is expressed in virtually all tissues and in many developmental stages. Yet, we have very little knowledge of its functions in these other sites. While it is well established that PTHrP can be processed into a series of different peptides, the biological significance of these different forms of PTHrP is poorly understood. Likewise, it is established that, in addition to its actions through the PTHR1, PTHrP can translocate to the nucleus. While preliminary data suggest that nuclear PTHrP is necessary for life in mice, we have very limited knowledge of how nuclear PTHrP may regulate either physiology or disease. Therefore, although much progress has been made in the 34 or so years since the identification of PTHrP, we actually have only a rudimentary understanding of the biology of this remarkable and ancient protein.

There is cumulative evidence that PTHrP contributes to disease processes in a variety of organs. It has been shown to affect the development and/or behavior of breast and other cancers. However, the reported functions of PTHrP in cancer cells have often been contradictory. Nevertheless, it does appear to have an important role in the progression of osteolytic bone metastases from multiple types of cancer. Mutations in the *PTHLH* gene have been shown to cause rare bone diseases, and alterations in PTHrP expression have been noted in diabetes and other disorders. Given its widespread expression and functions in multiple organs, it is likely that dysregulation of PTHrP expression or signaling will be found to contribute to the pathophysiology of other disease states.

Finally, targeting PTHrP signaling is likely to have therapeutic possibilities. In fact, recent advances in our understanding of the effects of PTHrP in bone biology have now culminated in the first synthetic PTHrP analog (abaloparatide) approved for the treatment of postmenopausal osteoporosis, completing the translational research cycle from bedside to bench and back again. Clearly, there is yet much to learn about PTHrP and its functions in biology and disease, with the future promise of new therapeutic uses for PTHrP or its analogs.

CALCITONIN SYNTHESIS, SECRETION, AND CELLS OF ORIGIN

The detailed history of the discovery of calcitonin (CT) has been expounded by Paul Munson and is a fascinating story of endocrinology.[1] The narrative describes how Copp and colleagues[2] discovered CT as a factor that opposes the action of parathyroid hormone (PTH) to contribute to the tight control of serum calcium in mammals. By perfusing the thyroparathyroid glands of dogs and sheep with high calcium concentrations, they obtained evidence for the secretion of a factor that rapidly lowers blood calcium levels, and called this factor CT. Although initially thought to be produced by the parathyroid gland, CT was subsequently found to be secreted by the thyroid gland in mammals.[3,4]

CT is produced by the C cells of the mammalian thyroid, from which its secretion is stimulated by an increase in serum calcium levels.[5] Interestingly, the distribution of C cells varies considerably across animal species. In some animals, CT-producing cells are found in other parts of the neck, including the thymus, and in fish and most birds CT is produced by the ultimobranchial glands. Whereas in mammalian development the ultimobranchial bodies fuse with the posterior lobes of the developing thyroid to become the C cells, in submammalian vertebrates these bodies remain separate. Interestingly, the CTs of ultimobranchial origin are highly potent in their actions on mammalian targets. The physiological significance of CT in fish and birds remains uncertain, although CT has been reported to suppress osteoclastic activity in the scales of freshwater and seawater teleosts.[6] Increased serum calcium is an important secretagogue for CT in normal and malignant C cells, and as the same extracellular calcium-sensing receptor (CaSR) that mediates decreased PTH secretion from parathyroid cells[7] is also found in C cells, it is likely to represent the primary molecular entity through which C cells detect changes in extracellular calcium and control CT release. Further suggesting that the CaSR is a physiological regulator of CT, the dose-response curve of CT to increases in serum ionized calcium was shifted to the right in CaSR heterozygous-ablated ($Casr^{+/-}$) mice.[7] Also consistent with this notion is the recent observation that CT release is sensitized to extracellular calcium by L-amino acids, as the CaSR is positively modulated by L-amino acids in the context of PTH secretion.[8]

Agents that elevate cyclic adenosine monophosphate (cAMP) in C cells may stimulate CT secretion, as cAMP analogs have this effect both *in vitro* and *in vivo*. Aside from calcium, secretagogues include the gastrointestinal hormones, such as gastrin, suggesting that CT may have a physiologic role postprandially as a hormone that assists uptake of calcium after a calcium-rich meal by preventing the efflux of calcium from bone into blood. The gastrin analog pentagastrin has been used clinically as a provocative test for CT secretion in patients with medullary carcinoma of the thyroid. Other gastrointestinal hormones, including glucagon, cholecystokinin, and secretin, are also capable of promoting CT secretion. Long-acting glucagon-like peptide-1 receptor agonists also stimulate CT secretion in rats and mice but reportedly have minimal or no ability to stimulate CT secretion in the normal C cells of primates and humans.[9] Other hormones that influence calcium homeostasis may also directly or indirectly influence CT secretion. 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) administration has been reported to increase plasma CT levels. Both CT and $1,25(OH)_2D_3$ levels are raised in pregnancy and lactation, leading to the suggestion that CT may act to protect the skeleton in the face of increased calcium demand during lactation (see later).[9]

Basal serum levels of CT in normal human subjects are very low (<10 pg/mL [3 picomolar]), and their measurement requires sensitive assays that are specific for the monomeric form of the molecule.[10]

Circulating levels of CT are increased in several pathologic states, particularly CT-secreting tumors, so that patients with medullary carcinoma of the thyroid can have highly elevated CT levels.[11] In addition to the CT monomer (~3500 Daltons), high molecular weight forms circulate, and elevated levels of these molecules can be useful diagnostically in certain situations, such as acute pancreatitis and infection/inflammatory conditions.[12] It has been reported that procalcitonin (proCT) is toxic, and that immunoneutralization with immunoglobulin G that is reactive to this molecule significantly improves survival in animal models of sepsis.[13] A prospective, population-based study of 3322 individuals demonstrated an association between plasma proCT levels and all-cause and cancer mortality in apparently healthy men, but not women.[14]

CALCITONIN CHEMISTRY

The amino acid sequence of CT has been determined for many species, with the common features being that it is a 32–amino acid peptide with a C-terminal proline amide, as well as a disulfide bridge between cysteine residues at positions 1 and 7 creating an N-terminal ring structure.[15] Based on their amino acid sequence homologies, the different CTs (Fig. 49.1) are classified into three groups: (1) *artiodactyl*, which includes porcine, bovine, and ovine; (2) *primate/rodent*, which includes human and rat; and (3) *teleost/avian*, which includes salmon, eel, sardine, goldfish, and chicken. The common structural features of the CT molecule contribute importantly to biological activity. The standard assay for CT bioactivity that has been used since the discovery of CT is the measurement of the hypocalcemic response in young rats. Subsequently, receptor-based assays have been used also, and structure/function relationships are largely consistent in these various assays. The relative order of biological potency of the CTs is, in general, teleost≥artiodactyl≥human, although the absolute biological activities vary considerably between the CT receptors (CTRs) of different species and between receptor isoforms within species. Studies of substituted, deleted, and otherwise modified CTs have provided considerable information regarding structure/activity relationships of the CT molecule, showing, for example, that the ring structure serves to stabilize the molecule. The disulfide bridge of the ring can be chemically substituted by an N-N bond, as in aminosuberic eel CT, and this modification yields an extremely stable and fully potent CT variant.[16] The sequence differences among species are concentrated in the middle portion of the molecule, and these differences contribute to the wide variations in biological potency. However, the outcomes of studies of structural requirements for biological activity vary with the different biological assays used, and the type of receptor (see later sections on CTR isoforms and the influence of the coreceptor molecules, receptor activity–modifying proteins [RAMPS]). For example, residues in the C-terminal half of salmon CT are more important for binding competition with the two rat CTR isoforms and the human CTR, whereas residues in the N-terminus are more important for interaction with the porcine CTR.[17]

CALCITONIN GENE

The human gene encoding CT is located in the p14-qter region of chromosome 11.[18] The complete sequences of the gene encoding human CT, and those of a number of other species, including rat, mouse, chicken, sheep, dog CT, as well as various species of fish CTs, have been determined. As with other peptide hormones, CT is synthesized as a larger precursor molecule, which is processed by cleavage and amidation before secretion. A 136–amino acid precursor has a leader sequence at the N-terminus that is cleaved during transport of the molecule into the endoplasmic reticulum. It is uncertain whether the N- and C-terminal flanking peptides that are released by the cleavage have any biological significance. A potentially important posttranslational modification of CT is that of glycosylation. The tripeptide sequence Asn-Leu-Ser found within the N-terminal ring structure of CT is invariate among the CTs of different species, and this sequence is an acceptor site for N-linked glycosylation. The biological significance of CT glycosylation has yet to be determined.

Calcitonin Gene Alternative Product

The CT gene encodes a second distinct peptide, known as CT gene–related peptide (CGRP), which is produced by tissue-specific alternative splicing (see ref 18 and Fig 49.2). The CGRP and CT mRNAs predict proteins that share sequence identity in the N-terminal regions but are almost entirely different in the C-terminal regions. The mature, secreted 32– and 37–amino acid CT and CGRP peptides, respectively, result from cleavage of both N-terminal and C-terminal flanking sequences at specific cleavage sites, as depicted in Fig 49.2. CT mRNA is found largely in the thyroid, and CGRP mRNA is found primarily in the nervous system,[19] although both mRNAs are expressed to a lesser extent in other tissues. Aberrant expression of CGRP may be seen in medullary thyroid carcinoma. Two different CT/CGRP genes, α and β, have been identified in humans and rats.

KEY POINTS

- Calcitonin (CT) is a peptide hormone that in mammals is produced in the thyroid gland, with a primary recognized action of regulating blood calcium, and its secretion is stimulated by an increase in serum calcium levels. The potency of CT action in different species varies considerably. CT is also produced in diverse tissues and acts in a paracrine fashion. The gene encoding calcitonin also encodes the peptide CGRP, which has a very different bioactivity profile.

Fig. 49.1 **Alignment of calcitonin (*CT*) sequences from different species.** The shaded amino acids indicate identity with salmon CT. All CTs have a disulfide-bridged loop between cysteines (C) at position 1 and 7, a glycine at position 28, and a proline amide at position 32. Amino acids 4, 5, and 6 are also conserved across all species.

CALCITONIN RECEPTORS

Receptor Gene

The *CTR* gene sequence for human and other species, including rat, mouse, rabbit, guinea pig, and several species of fish, has been reported, and the phylogenetic relationships between CTRs of mammalian and nonmammalian species have been well described.[20-22] Analyses of the corresponding predicted proteins revealed that these receptors comprise approximately 500 amino acids and belong to the class B subclass of G protein–coupled receptors, which includes the receptors for other peptide hormones, such as secretin, PTH, glucagon, glucagon-like peptide 1, vasoactive intestinal polypeptide, pituitary adenylate cyclase–activating peptide, and gastric inhibitory peptide.

The CTR, encoded by the *CALCR* gene, is greater than 90 kb and comprises 14 exons.[23] The complexity of *CALCR* is shared by the genes encoding other class II G protein-coupled receptors, and the overall structural organization and size of the human gene are similar in other species.[23,24] Isolation of the mouse *Calcr* revealed that the locations of introns within the coding region of the *mCTR* gene (exons E3–E14) are identical to those of the porcine and human *CALCR* genes. The predicted structure of the mefugu fish gene is more complex than that of the human gene, with an additional nine exons.[22] It is interesting to note that both fish and mammalian genes code for the microRNA-489, in intron 3, the function of which remains to be determined. As detailed below, different CTR phenotypes are generated by alternate splicing of the primary mRNA transcript.

The regulatory portion of the *CALCR* gene contains three putative promoters (P1, P2, and P3), giving rise to multiple CTR mRNA transcripts, which differ in the 5′ region of the gene and generate 5′-untranslated regions (UTRs) of very different lengths, in a tissue-specific manner.[24] Promoters P1 and P2 are used in osteoclasts, brain, and kidney, while the proximal promoter of the human *CTR* (*hCTRP1*) was transcriptionally active in all cell lines tested, with high-level activity dependent on an 11–base pair Sp1/Sp3 binding site. In contrast, promoter P3 appears to be osteoclast-specific and is sensitive to the osteoclast-inducing cytokine receptor activator of nuclear factor kappa-β ligand (RANKL), as well as the RANKL-induced transcription factor NFATc1, consistent with a role for the latter in regulating the *CALCR* gene in osteoclasts.[24]

The human *CALCR* gene is located on chromosome 7, at 7q21.3. In mice it is in the proximal region of chromosome 6, while the pig gene is located in chromosomal band 9q11-12. These pig and mouse chromosomal regions are homologous to 7q in humans. It is interesting to note that the mouse *Calcr* gene is expressed preferentially from the maternal allele in brain, with no allelic bias detected in other tissues, indicating that the mouse *Calcr* gene is imprinted in a tissue-specific manner.[25]

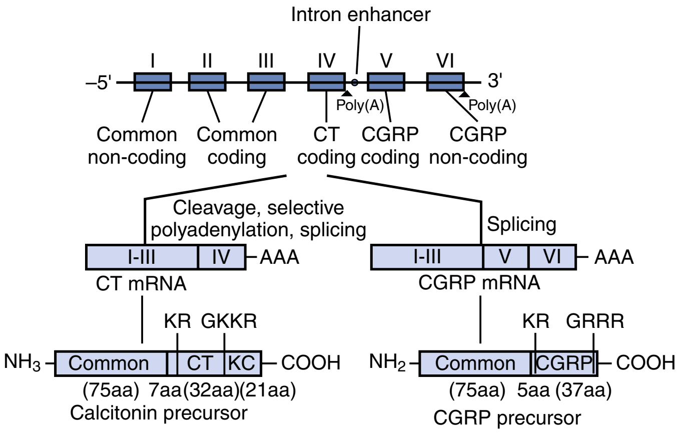

Fig. 49.2 Organization of the calcitonin (*CT*)/calcitonin gene–related peptide (*CGRP*) gene, illustrating alternative patterns of processing of the primary transcript and subsequent protein processing. The exons are denoted I through VI in Roman numerals, and introns are represented by a single line (not to scale).

Receptor Isoforms

CTRs show heterogeneity, with multiple receptor isoforms that result from alternative splicing of the CTR mRNA primary transcript. The human receptor, of which there are at least five splice variants, is the most extensively studied. The most common hCTR splice variant occurs in putative intracellular domain 1, generating a 16–amino acid insert in this domain (I_{1+} or CTb isoform); the insert-negative isoform is termed CTa.[26] Additional splice variants have been identified in other species. In the pig, an inserted sequence (the I1 insert) is generated by alternate splice sites located in exon 8, while in humans the I1 insert occurs on a separate exon. In rodents, alternate splicing leads to two receptor isoforms, which differ from the human isoforms: these have been termed C1a and C1b, and vary by the presence (C1b, or E_{2+}) or absence (C1a), respectively, of a 37–amino acid insert in the putative second extracellular domain.[27] There is no evidence for expression of the rodent C1b isoform in humans. In rabbits, an additional splice variant in which the exon encoding transmembrane domain 7 is spliced out (ΔTM7, or delta e13) has been isolated.[28]

The insertions and deletions in the CTR structure lead to altered receptor function, including ligand binding, signal transduction, and regulation of receptor expression. For the E_{2+} variants, there is a loss of affinity for peptides exhibiting weak α-helical secondary structure, such as human CT, whereas peptides with strong helical secondary structure, such as salmon CT, maintain high affinity at this receptor.[29] An interesting variant of the hCTR that lacks the first 47 residues of the N-terminus, the Δ1-47 variant, retains expression at the cell surface but has altered functionality in terms of ligand (amylin [AMY]) binding, depending on which RAMP coreceptor (see below) it associates with.[30] The CTb (I_{1+}) hCTR isoform displays similar affinity to the CTa (I_1) variant for CT-like peptides but has markedly altered G protein–coupling efficiency. However, the presence of the 16–amino acid insert leads to complete loss of intracellular calcium mobilization. CT signaling through the CTb hCTR via G_s is cell type–dependent but overall is decreased, leading to a 10- to 100-fold reduction in the potency of peptides for stimulation of cAMP production.[29] It is interesting to speculate about the functional significance of the different receptor isoforms, particularly those with apparently impaired signaling capacity. Accumulating evidence suggests that G protein–coupled receptors can form homodimers and heterodimers, and that these interactions can crossmodulate the activity of the partners. Indeed, in the case of the rabbit CTR (ΔTM7), Seck et al.[31] reported that this isoform can complex with the CTa isoform and inhibit its cell surface expression and activity, thus exerting an endogenous dominant negative effect on CTR signaling.

Receptor Polymorphisms

There are reports of polymorphisms in the *CTR* gene associating with bone disease, specifically fracture risk, [32-35] although these studies are often underpowered to draw conclusions. There is a reported association between the expression of the CTa receptor mRNA in circulating monocytes of postmenopausal, but not premenopausal, women and their serum levels of bone alkaline phosphatase and urinary deoxypyridinolone.[32] The authors suggested a link between CTR expression and increased bone resorption postmenopausally. In other work, a polymorphism within the *CTR* gene coding sequence arising from a single nucleotide substitution was identified that leads to either a proline (CC genotype) or a leucine (TT genotype) at amino acid 447 in the human CTa receptor (amino acid 463 of the hCTb receptor), with heterozygotes designated TC.[33,34] The prevalence of different polymorphisms varies markedly between different ethnic groups.

The influence of the *CTR* polymorphism on bone mineral density (BMD) has been studied by multiple investigators. A number of studies have identified significant correlations between *CTR* genotype and osteoporotic markers (BMD) and fracture risk; however, there is considerable divergence among studies regarding which genotype is more favorable, with the same polymorphism being correlated with both increased BMD and decreased BMD.[33,34] The *CTR* genotype has also been linked to body weight in premenopausal Japanese women, and to incidence of kidney stones. These studies have not identified significant functional differences in ligand binding or cAMP generation between the two polymorphic variants.[35] A large number of other, probably silent, polymorphisms in *hCTR*, whose frequency varies among ethnic groups, have been identified.

In assessing polymorphism association studies, it is important to appreciate issues of study power, ethnicity, gene interactions, and other confounders. Genome-wide association studies have so far not linked the CTR with metabolic bone changes. Surprisingly, however, linkage studies in rats have identified the *CALCR* gene as a candidate for regulating susceptibility to herpes simplex type 1 neuronal infection leading to encephalitis.[36]

Receptor Distribution

Direct evidence for binding of CT to osteoclasts was obtained from the work of Nicholson et al.,[37] who used *in vitro* autoradiography to demonstrate ^{125}I-sCT binding specifically to mono- and multinuclear osteoclasts and their precursor cells. Expression of the CTR became a required phenotypic feature to establish cells as osteoclasts. Radioligand binding studies in tissue sections, membranes, and cultured cells have revealed extensive extraskeletal distribution of CTRs. These extraskeletal sites include kidney, brain, pituitary, placenta, lung, lymphocytes, testis, and spermatozoa, as well as cancer-derived cells from lung, breast, pituitary, and embryonal carcinoma.[38]

The centrally mediated actions of CT are discussed later and correlate well with the locations of CT binding sites. Autoradiographic mapping, where ^{125}I-sCT was used as the radioligand, revealed high binding densities associated with parts of the ventral striatum and amygdala, the hypothalamic and preoptic areas, as well as most of the circumventricular organs. High-density binding also occurs in parts of the periaqueductal gray, the reticular formation, most of the midline raphe nuclei, parabrachial nuclei, locus coeruleus, and solitary tract nucleus.[39,40] As is discussed later, CT and AMY receptors derive from the same gene product, and consequently care needs to be taken in extrapolating the potential significance of CTR mRNA expression for CT biology. CTR mRNA expression has been confirmed in many of the sites with demonstrated ^{125}I-CT binding, including kidney, brain, lung, placenta, and osteoclasts, and a number of cancer cell lines. In addition, CTR mRNA studies have also provided evidence for previously uncharacterized sites of CTR expression, including prostate, normal and neoplastic breast, and thyroid.[38] There is also evidence for CTR expression in osteocytes in bone.[41]

Calcitonin Receptors and Receptor Activity-Modifying Proteins

Members of the CTR family, and the CTR itself, can assume different ligand binding phenotypes by two distinct mechanisms. Firstly, and as already discussed, receptor binding affinity and signaling depend on the specific receptor isoform. Secondly, different functional receptors arise from association of the CTR with coreceptor molecules. Specifically, molecules termed RAMPs can associate with the CTR to alter ligand affinity[42] and downstream signaling.[43] The RAMP family comprises three single transmembrane proteins, RAMP 1, 2, and 3, which act to assist trafficking of receptors to the cell surface and/or physically associate with the receptor to modulate ligand binding and specificity. CTRs do not require RAMPs to translocate to the cell surface or to exhibit a classic CTR phenotype, that is, with highest affinity for CT. In the case of the CTR, RAMP-CTR complexes give rise to receptors for AMY (Fig. 49.3), with distinct receptor phenotypes depending on which RAMP is complexed with the receptor.[44,45] The CTR/RAMP 1 complex, in addition to being a high-affinity AMY receptor, also interacts strongly with CGRP.[44] Both RAMPs and receptors are subject to dynamic regulation.[46]

KEY POINTS

- The calcitonin receptor (CTR) is a G-protein coupled protein that spans the cell membrane seven times. It is produced in a number of species-specific isoforms that have different activities. It also associates with the coreceptor molecules, receptor activity-modifying proteins, which confer different ligand recognition capacity. The CTR has a wide tissue distribution associated with the different actions of calcitonin (CT) and CT-like peptides.

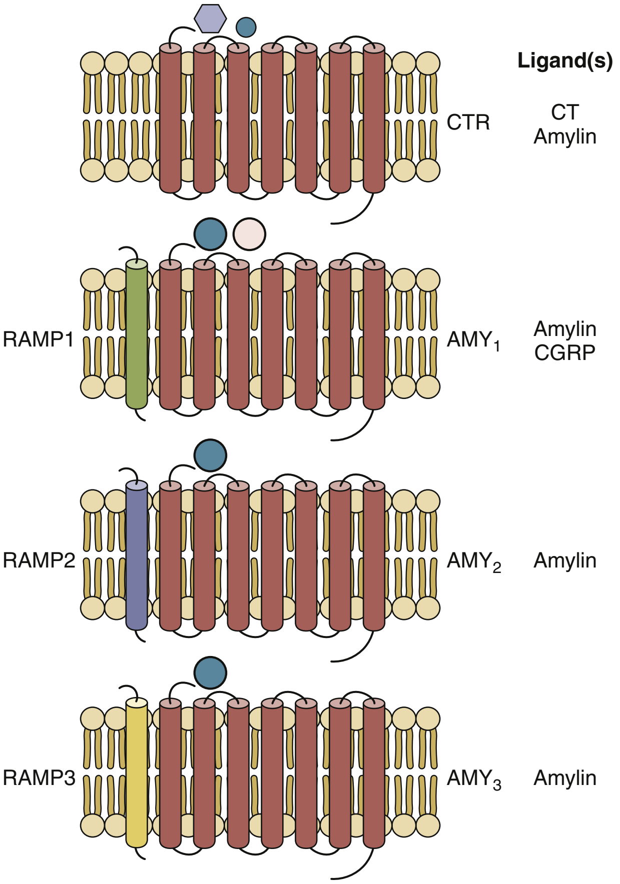

Fig. 49.3 **Calcitonin receptor (*CTR*) ligand specificity regulation by receptor associated–modifying proteins (*RAMPS*).** Shown are ligand specificities and relative affinities for calcitonin (*CT*), amylin, and calcitonin gene–related peptide (*CGRP*), respectively, of CTR alone or when associated with RAMPs 1, 2, or 3, respectively. (Modified from Hay DL, Garelja ML, Poyner DR, et al. Update on the pharmacology of calcitonin/CGRP family of peptides: IUPHAR Review 25. *Br J Pharmacol.* 2018;175:3–17.)

Calcitonin–Calcitonin Receptor Signaling

G protein–coupled receptors can interact with and signal through multiple G proteins (Fig. 49.4), with G_s activation stimulating adenylate cyclase activity, cAMP production, and protein kinase A (PKA)-induced signaling pathways. This occurs in osteoclasts and in the kidney, with the CT responsiveness spatially paralleling the distribution of CTRs in the latter tissue. CT induction of cAMP has now been documented in a large number of CTR-bearing cells, which include LLC-PK1 pig kidney cells and cancers of lung, breast, prostate, and bone. Receptor cloning and expression studies have confirmed that cAMP production is an important component of CTR-mediated signaling.[15,29,38]

In mice, the response of osteoclasts to CT appears to be mediated predominantly by the PKA pathway,[47,48] although inhibition of osteoclast-mediated bone resorption by CT can be mimicked by both dibutyryl cAMP and phorbol esters or blocked by protein kinase inhibitors. Coupling of the CTR to G_q can also activate phospholipase C, leading to increased cytosolic calcium and triphosphate levels and activation of protein kinase C.[49] Thus, in human osteoclasts, activation of protein kinase C pathways appears to be the predominant mechanism of CT-mediated osteoclast inhibition.

CT induction of interleukin (IL)-6 production in pituitary folliculostellate cells requires both PKA and protein kinase C (PKC) signaling pathways.[50] In hepatocytes, even at very low concentrations, CT is capable of increasing cytosolic calcium.[51] CT-induced differentiation of early rat embryos is dependent upon intracellular calcium mobilization.[52] It is interesting to note that, although CT inhibits proton extrusion from osteoclasts,[53] it can increase hydrogen ion efflux from nonosteoclastic cells in a PKC-dependent manner.[54] The biological significance of this activity is not clear. CT-induced changes mediated by cAMP or intracellular calcium in LLC-PK1 pig kidney cells are cell cycle–dependent.[55] Expression of cloned receptors in a variety of cell types has now conclusively shown that CTRs of human, rat, and porcine origin are capable of signaling through both cAMP- and calcium-activated second messenger systems.

CT treatment of CTR-expressing cells in the presence of extracellular calcium initiates a sustained rise in intracellular calcium, the extent of which is dependent on the concentration of the extracellular calcium and is proportional to the receptor density.[56] Because osteoclasts, which express high levels of CTR, are reportedly exposed to calcium concentrations as high as 26 mM during bone resorption, this phenomenon may have particular relevance for this cell type. CT and extracellular calcium can both cause intracellular calcium transients in isolated osteoclasts, and each agent greatly augments the signal produced by either agent alone.[57]

CTR-mediated activation of the mitogen-activated protein kinase (MAPK) pathway has been described,[58-60] with a role for both G_q and $Gi_{/o}$ proteins—the latter principally via βγ G protein subunits, as is commonly the case for other G protein–coupled receptors. There is also evidence that CT can influence cell attachment by modulating components of focal adhesions and the cytoskeleton.[59] CT treatment of osteoclasts disrupts the F-actin ring that is thought to correspond to the sealing zone[61,62] and increases the tyrosine phosphorylation of paxillin and focal adhesion kinase. In rabbit osteoclasts, these actions were mediated by PKC.[59] These actions of CT, together with decreased osteoclast motility, cytosol retraction, and disassembly of podosomes, have been linked to modulation of the activity and intracellular localization of Pyk2 and Src in osteoclasts.[63] It has also been shown, in nonosteoclastic cells, that CT can cause cell death by aniokis as the result of loss of cell attachment.[64]

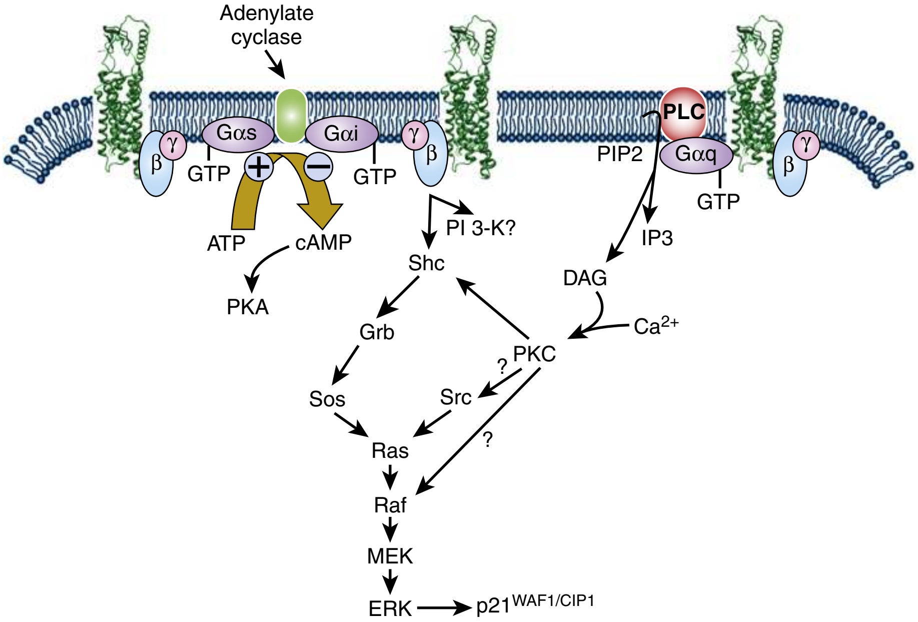

Fig. 49.4 Calcitonin (CT) activation of the calcitonin receptor activates multiple signaling pathways. Coupling to $G_{\alpha i}$ is seen less frequently and may be owing, at least in part, to a protein kinase C (*PKC*)-dependent inhibition of G_i. The balance of activation of different G proteins and effectors is critical for the cell-specific actions of CT. Also illustrated is the current understanding of CT-induced mitogen-activated protein kinase (MAPK) activation, as delineated in stably transfected HEK-293 cells. ERK1/2 phosphorylation requires both PTX-sensitive G proteins (presumably G_i via βγ subunits) and G_q. The latter leads to rises in intracellular calcium and activation of PKC, and both contribute to ERK phosphorylation. At least part of the activation occurs following phosphorylation of Shc and mobilization of its downstream effectors. Activation of ERK increases phosphorylation of $p21^{WAF/CIPI}$ and modulation of cell growth. Although strongly activated by CTa receptors, G_s is not involved in activation of MAPKs.

Receptor Regulation

Regulation of the level and/or affinity of cell surface receptors is a key component of the physiologic and pathophysiologic responses to both endogenous and pharmacologically administered agents. The CTR is subject to both homologous (CT-induced) and heterologous regulation. CT-induced downregulation of the CTR was initially demonstrated in various transformed cell lines and subsequently in primary kidney cell cultures. Given that the induction by CT of resistance to its own action in osteoclasts is such a specific process, and that it correlates so closely in dose dependence to CT efficacy as an agonist,[65] it appears to be an important accompaniment of CT action.

CT-induced receptor downregulation, resulting in a specific loss of cell surface receptors, occurs via energy-dependent internalization of the ligand-receptor complex, in which the principal internalization pathway involves processing of the receptor-ligand complex into lysosomes and subsequent degradation of the receptor. It is worth noting that the kinetics of internalization of human CTRs appears to be isoform-specific, with the I_{1+} variant being resistant to internalization.[26] Receptor regulatory responses to CT are also likely to be cell- or tissue-dependent. For example, in mouse or rat osteoclasts, a potent downregulation of CTR mRNA appears to be mediated by a cAMP-dependent mechanism, in addition to downregulation of the receptor by internalization.[66] Similar CT-mediated CTR regulation is also observed in human osteoclasts, but as stated above, activation of PKC pathways is thought to be the predominant mechanism of CT-mediated osteoclast inhibition in human osteoclasts. Different mechanisms may apply in nonosteoclastic cells, as downregulation of CTRs in UMR106-06 osteoblast-like cells and T47D breast cancer cells is not accompanied by changes in CTR mRNA levels.[66] The CT-induced reduction in CTR mRNA in osteoclasts appears to be due principally to destabilization of receptor mRNA.[67] The 3’-UTR of the mouse and rat CTR mRNA contains four AUUUA motifs, as well as other A/U--rich domains, which can function as signals for rapid mRNA inactivation. Thus, addition of A/U-rich CTR 3’-UTR sequences considerably shortens the mRNA half-life of a reporter gene, and evidence shows the involvement of AUF1 p40, HuR in the regulation of CTR mRNA.[67] Whether this regulation involves the participation of microRNAs, which have been shown to regulate the expression of other CGPRs, has not yet been reported.

Heterologous regulation of CTR includes regulation by glucocorticoids. In mouse osteoclast cultures, dexamethasone increased the level of cell surface CTR by upregulation of receptor mRNA levels, which was mediated at the level of transcription.[68] Moreover, the CT-mediated decrease in cell surface receptor and mRNA was attenuated by dexamethasone. Increased production of CTR in response to glucocorticoid stimulation also occurs in the human T47D breast cancer cell line, where cortisol is actually required for the expression of CTRs, suggesting that this may be a common regulatory mechanism for induction of CTR expression. It is worth noting the clinical evidence suggesting that glucocorticoids, given together with CT, might prevent to some extent the CT-induced resistance to its own action.[69]

KEY POINTS

- Calcitonin (CT) binding to its cognate receptor (CTR) results in intracellular signaling, predominantly via the protein kinase A– and protein kinase C–activated signaling pathways. Signaling stimulates different, cell-dependent actions. In addition, in at least some target cells, such as osteoclasts, CT signaling initiates downregulation of the CTR, via cell internalization of the receptor and reduced synthesis of the CTR.

CALCITONIN PHYSIOLOGY

The physiological roles of CT are not fully understood, although the repertoire of actions of the peptide has expanded considerably since its discovery. As a hormone, CT has been described as “enigmatic”[70] or “in the process of becoming vestigial,”[71] because there are no apparent deficiency syndromes and no obvious effects of high concentrations because of CT-producing tumors. However, there is clearly more to learn, and important roles for locally produced CT have been uncovered, as detailed here.

Calcitonin in Growth and Development

The presence of CT and its receptors in a large number of cell types and tissue sites suggests multiple physiological roles. CTRs have been identified in bone, kidney, brain, pituitary, testis, prostate, spermatozoa, breast, lung, and lymphocytes, as well as in cancer-derived cells from lung, breast, prostate, pituitary, bone (osteoclastoma, osteogenic sarcoma), and embryonal carcinoma.[40] One potential role of CT relates to its ability to potently modulate the growth and/or viability of some CTR-bearing cells. Treatment with CT has been shown to stimulate the growth of human prostate cancer (PC) cells, in which the peptide increases both intracellular calcium and cAMP levels.[72] Conversely, knockdown of CTR expression in these cells induced apoptosis and growth arrest.[73] The effects of CT on growth are clearly cell type–dependent, as CT treatment repressed the growth of T47D human breast cancer cells, an action proposed to be mediated by the specific activation of the type II isoenzyme of the cAMP-dependent protein kinase.[74] In HEK-293 kidney cells overexpressing the human CTR, CT inhibited cell growth and caused an accumulation of cells in the G2 phase of the cell cycle, associated with a prolonged increase in $p21^{WAF1/CIP1}$ expression[75] and sustained activation of the p42/44 MAPK proteins.[76]

There is evidence consistent with the involvement of CT also in the early events of embryo development. CT was shown to promote development of preimplantation embryos, an action that was antagonized by p38-MAPK inhibition or anti-CT antibody treatment.[77] CT may be involved in both blastocyst implantation and development of the early blastocyst,[78] and CT downregulates E-cadherin expression in rat uterine epithelium during implantation and upregulates integrin β3 expression in mouse endometrial epithelial cells.[79] CT also promotes the outgrowth of trophoblast cells on endometrial epithelial cells, perhaps thereby facilitating embryo implantation.[80] Reduced endometrial expression of CT and β3 integrin could contribute to unexplained infertility in humans.[81] Indeed, CT administration improves endometrial receptivity,[82] and intraperitoneal CT treatment of pregnant or pseudopregnant mice significantly increased blastocyst implantation.[83] These actions of CT may explain the reports of embryonic lethality of global deletion of the *Calcr* gene in mice.[61,84] The embryonic expression of mouse CTR suggests that CTRs may play important roles in morphogenesis.[85]

It has been reported that CT is expressed in the pregnant mouse mammary gland, exclusively in the luminal epithelial cells, from which it is secreted, and that its expression is progesterone-dependent.[86] It was found that CT induction spatiotemporally correlates with increases in progesterone-induced mammary gland proliferation and structural remodeling, suggesting that CT may be involved in one or both of these progesterone-dependent processes. It would be of interest to know whether the established central roles of RANKL in these processes involve CT. As mentioned, CT can inhibit cell proliferation or can have mitogenic actions. CT may also have a role in cell survival, and as discussed above, has been claimed to be protective of drug-induced apoptosis in osteoblast-like, osteocyte-like, and PC cell lines, and to promote the survival of osteoclasts.[87] On the other hand, CT has been found to potentiate neuronal death because of oxygen and glucose deprivation, and to be proapoptotic in serum-deprived cells.[88]

Calcitonin in Calcium Stress: Pregnancy and Lactation

CT was initially understood to be an inhibitor of bone resorption, functioning to regulate loss of calcium (and perhaps phosphate) from the skeleton, particularly in times of stress on skeletal calcium conservation, such as during pregnancy, lactation, and growth.[70] An early observation was that thyroidectomized patients had a significantly prolonged elevated serum calcium following a calcium infusion when compared with thyroid-intact control patients, which the authors were unable to account for mechanistically.[89] More recent studies suggest that the ability of CT to reduce serum calcium levels following an exogenous calcium load can be at least partly explained by reducing the efflux of calcium from bone. Thus, in genetically modified mice, in which the CTR is deficient either globally or specifically in osteoclasts, $1{,}25(OH)_2D_3$ treatment induced greater bone resorption and exacerbated hypercalcemia compared with littermate controls.[90] These data suggest that the action of CT to protect against hypercalcemia is largely mediated by the CTR on osteoclasts. In young and growing animals, in which rapid bone modeling and remodeling are required for morphogenesis of the skeleton, CT may act as a regulator of extracellular fluid calcium. Thus, exogenous CT causes a lowering of blood calcium levels in the young rat, a response which is used as the *in vivo* assay of CT, while its calcium-lowering effect becomes less marked with increasing age of the animal. Despite this, the ability of CT to counteract the effects of a calcium load is not impaired with age, at least in the rat.[91]

It is important that bone resorption is tightly regulated, and CT is the only hormone known to be capable of carrying out this function by acting directly on osteoclasts. However, in normal adult human subjects, even quite large doses of exogenous CT have little effect on basal serum calcium levels. This is not surprising, as the extent of bone resorption is much reduced in maturity. However, in those subjects, in whom bone remodeling is increased (e.g., in thyrotoxicosis and Paget disease), CT treatment acutely inhibits bone resorption and lowers serum calcium levels.[92] The relative physiological actions of CT and local inhibitors of osteoclastic resorption, such as osteoprotegerin, remain to be clarified.

An antiresorptive role for CT in maturity is likely to be more important in circumstances in which skeletal integrity is at particular risk, for example with the high calcium demand that occurs during lactation. In both humans and mice, circulating levels of CT are elevated during lactation,[93] supporting the notion that CT opposes the bone-resorbing actions of mammary-derived PTH-related peptide to protect the maternal skeleton from excessive resorption during lactation.[94] Evidence in support of such an important physiological role for endogenous CT in protecting against bone loss is provided by experiments showing that, in thyroparathyroidectomized rats (lacking CT) treated with PTH, cancellous bone loss was greater than that in similarly treated sham-operated (CT-replete) controls.[95] In addition, mice in which the *CT/CGRP* gene was ablated showed a severe drop in bone mineral content during lactation as a result of a doubling in osteoclast numbers, which was prevented by treatment with CT but not CGRP.[96] Somewhat surprisingly, in mice lacking the *Calcr* gene, bone resorption was not increased following lactation, suggesting that this protective effect of CT on bone in CT/CGRP knockout mice is not mediated via the activity of CTR on osteoclasts, but perhaps involves another member of the CTR family.[97] This study also uncovered a potentially important role for the CTR located on osteocytes to protect the maternal skeleton. Here, activation of the osteocyte CTR inhibited lactation-induced osteocytic osteolysis,[97] the process by which osteocytes mobilize calcium from the perilacunar bone matrix.[98] Recovery of the skeleton does not appear to be dependent on CT/CGRP[99] or CTR[99a] as the maternal skeleton of mice deficient in either ligand or receptor recovers to baseline postweaning. [99]

As discussed in more detail later, physiological roles in calcium homeostasis potentially also exist for other members of the CT family. These include AMY, CGRP, CTR-stimulating peptide (CRSP), and intermedin (IMD).[100]

KEY POINTS

- Calcitonin (CT) appears to have important roles in pregnancy and lactation. Evidence suggests its involvement in both blastocyst implantation and development of the early embryo. In addition, it appears that CT is involved in preparation of the mammary glands for lactation, as well as protection of the skeleton from excessive calcium loss during lactation.

Calcitonin in Bone: Osteoclasts. The first evidence of the mechanism of action of CT was obtained by showing in organ culture of bone that CT inhibited bone resorption.[101] Inhibition of bone resorption appeared to be explained by a direct action on osteoclasts because CT treatment of resorbing bone *in vitro* resulted in rapid loss of osteoclast ruffled borders[102] and decreased release of lysosomal enzymes. Evidence *in vivo* was also consistent with an inhibitory action upon bone resorption. Loss of ruffled borders in osteoclasts was seen in patients with Paget disease, from whom bone biopsies were taken before and 30 minutes after an injection of CT.[103] In the same clinical study, CT was noted to decrease the number of osteoclasts, in addition to altering their ultrastructure. CT infusion in rats led to an immediate reduction in the rate of excretion of hydroxyproline, consistent with inhibition of osteoclastic breakdown of bone collagen.[92] Other studies led to similar conclusions, with no evidence to suggest any increase by CT in the active uptake of calcium by bone.[104]

Mammalian osteoclasts possess abundant, specific, high-affinity receptors for CT, and CT stimulates cAMP formation in osteoclasts dose-dependently,[37] as well as increasing intracellular free calcium levels and PKC activity. Isolated osteoclast cells are exquisitely sensitive to CT, and the direct effect of CT is a rapid inhibition of cell activity, reflected in cessation of osteoclast motility and contraction.[102] Interestingly, although isolated osteoclasts remained quiescent as long as CT was present, they regained activity when osteoblasts were added to the culture. This "escape" of osteoclasts from inhibition by CT took place at a rate proportional to the number of osteoblasts, with which they were in contact. PTH had no effect on CT-reduced cytoplasmic spreading of isolated osteoclasts unless osteoblasts were cocultivated with the osteoclasts, in which case PTH caused a marked increase in cytoplasmic spreading of osteoclasts. These were the first direct observations of actions of hormones on isolated bone cell preparations containing osteoclasts.

The molecular mechanisms by which CT directly and rapidly decreases osteoclast function have been extensively investigated. The rapid effects of the hormone involve cytoskeletal molecules, following generation of several intracellular second messengers. Early events in CT signal transduction have been studied in a variety of cell types and are described in greater detail above. The other means by which CT might inhibit resorption is through inhibition of osteoclast formation, and here the evidence is conflicting. For example, a study in which developing mouse osteoclasts were treated with low concentrations of CT showed no reduction in osteoclast formation.[105] However, the multinucleated osteoclasts that formed in the continuous presence of exogenous CT did have fewer nuclei, suggesting that CT somewhat reduced the fusion of mononuclear cells. In contrast, several reports describe the inhibition of osteoclast-like cell formation by CT in bone marrow cultures of human, baboon, and mouse origin. More recent studies, in which osteoclasts were formed from mouse bone marrow macrophages under the influence of RANKL and macrophage colony stimulating factor, reported that 1 nM CT greatly reduced the formation of multinucleated osteoclasts, while having minimal effect on total tartrate-resistant acid phosphatase (TRAP) activity.[100] In elegant *in vivo* studies in mice, Ikegame et al.[65] showed that a CT-induced drop in serum calcium was linked temporally to the loss of osteoclast ruffled borders. Further, frequent dosing of the animals resulted in insensitivity to CT, with recovery of osteoclast ruffled borders and return of serum calcium to control levels in the presence of CT. It was significant that treatment of mice with CT initially rendered osteoclasts unable to bind ^{125}I-sCT, which recovered after a single treatment but not with repeated treatments.[65] These findings may be relevant to the mechanism of "escape" from CT that is observed clinically.

Calcitonin in Bone: Osteoblasts, Osteocytes, and Bone Formation. Although the best understood action of CT in bone is as an antiresorptive agent, numerous reports have described actions also on cells of the osteoblast lineage, and both direct and indirect effects on bone formation. CT increased cell proliferation, shown by [^{3}H]thymidine incorporation in embryonic chicken calvariae, in the transformed murine calvarial cell lines MMB and MC-3T3-E1, and in primary cultures of cells prepared from newborn mouse calvaria. CT was also shown to stimulate [^{3}H]thymidine incorporation in primary human osteoblasts[106] and to increase expression of insulin-like growth factors by human SaOS-2 cells. It should be noted that data failing to show such effects of CT have also been published. In addition to the fact that relatively high concentrations of CT were used in these early experiments, results with primary osteoblasts should be interpreted with caution, because calvarial osteoblast preparations are usually contaminated with other cell types, including osteoclast precursors and primary osteoblast preparations contain a substantial proportion of bone-specific macrophages, termed "osteomacs." Although at the level of resolution of CTR autoradiography, osteoclasts are the only discernible bone cell CT targets,[37] CTR mRNA and protein expression have since been demonstrated by immunohistochemistry in mouse osteocytes *in situ*, with rapid loss of detectable CTR following removal of these cells from bone.[41] The presence of the CTR in osteocytes can explain an increase in the osteocyte-secreted molecule, sclerostin, in the bones of CT-injected mice.[41] In addition, CT at high concentrations was associated with a small increase in cAMP and with protection of MLO-Y4 osteocyte-like cells from apoptosis induced by etoposide, tumor necrosis factor α, or dexamethasone. It has also been claimed that CT can hasten and improve the process of fracture healing in normal and osteoporotic rats. However, the mechanism for this "anabolic" response could be similar to that of bisphosphonates, which have also been shown to enhance the strength of the healed fracture, apparently by modulating resorption during the remodeling phase of bone repair. It could also relate to possible stimulation of angiogenesis by CT, which has been shown for human microvascular endothelial cells, albeit at supraphysiologic concentrations.

Experiments deleting the *CT* and *Calcr* genes in mice have provided important insights into the physiological significance of CT. Ablation of the *CT/CGRP* gene resulted in viable and fertile mice, with no production of CT or CGRPα.[99] These mice were much less able than wild-type mice to overcome the hypercalcemia induced by a calcium load,[99] and they lost excessive bone during lactation.[107] Surprisingly, however, the mice had increased bone mass, with histomorphometric parameters showing increased bone formation.[107] An increased bone formation phenotype was not found when CGRPα-deficient mice were examined, indicating that the increased bone formation was attributed to CT deficiency, and these results called for a reappraisal of the physiology of CT. The CT/CGRP-deficient mice were protected against ovariectomy-induced bone loss,[107,108] but it was striking that, after 6 months of age, these mice showed severe cortical bone porosity, even though indices of increased bone formation were maintained.[109,110] Taken together, the observations are indicative of an inhibitory effect of CT on both bone formation and bone resorption.

The concept of a negative regulatory role for CT on bone formation was strengthened by the outcome of studies by Dacquin et al.[84] in mice, in which the CTR was genetically manipulated. Homozygous deletion of the *Calcr* gene in mice was embryologically lethal, and this was thought to be because of a placental effect. The *Calcr*$^{+/-}$ mice, however, exhibited a bone phenotype virtually indistinguishable from the *CT/CGRP*$^{-/-}$ mice, with increased bone mass and increased bone formation on histomorphometry. Studies with mice that had substantial knockdown of the CTR also provided evidence of increased indices of bone formation.[65] Together, these results lead to the conclusion that, at least in mice, the removal of CT production or CT action via the CTR results in an increased amount of bone, again supporting a physiological role for CT as a tonic inhibitor of bone formation.

Several possible mechanisms for an effect of CT on bone formation have now been uncovered. Firstly, mouse and rat osteocytes express the CTR, and salmon CT treatment of rats increased sclerostin expression in the bones (Fig. 49.5).[41,111] Sclerostin is a negative regulator of bone formation and acts to inhibit anabolic responses in bone by blocking Wnt signaling. It was shown by microarray analysis of bone RNA and by immunohistochemistry that CT treatment both induced sclerostin mRNA in rat long bones and mouse calvariae and increased the number of sclerostin positive osteocytes in cortical bone from the tibia.[41] These actions are predicted to decrease local bone formation, but they may only be of physiological relevance in young animals. It was subsequently shown that, although the CTR was readily detected in osteocytes in 3-week-old mice, CTR levels declined with age and were undetectable by 49 weeks of age.[111] Secondly, CT has been shown to negatively regulate osteoclastic expression of the *Spns2* gene,[1112] which in turn encodes a transporter for sphingosine 1-phosphate (S1P), a reported osteoclast-osteoblast coupling factor.[113] Thus, CTR-deficient mice show increased S1P levels, which the authors demonstrated is linked to increased bone formation. There are multiple potential twists and caveats in this story, which have been expanded upon in separate publications,[114,115] in which the authors speculated that "a notable conclusion from this work is that the physiological function of CT in bone differs entirely from its pharmacological function."

KEY POINTS

- In bone, calcitonin has potent inhibitory actions on osteoclasts and additional actions on osteocytes, with evidence for both a protective role in the skeleton during lactation and for paradoxical inhibition of bone formation via induction of osteocyte production of the Wnt pathway inhibitor, sclerostin.

Renal Actions of Calcitonin

When infused into thyroparathyroidectomized rats, CT caused a dose-dependent phosphaturia, although this was minor in comparison with the phosphaturic effect of PTH. This was demonstrated in human subjects also, however in several species CT failed to have any effect on phosphate excretion. Thus it seems unlikely that the phosphaturic effect is of any major physiologic significance. A number of other renal effects of CT have

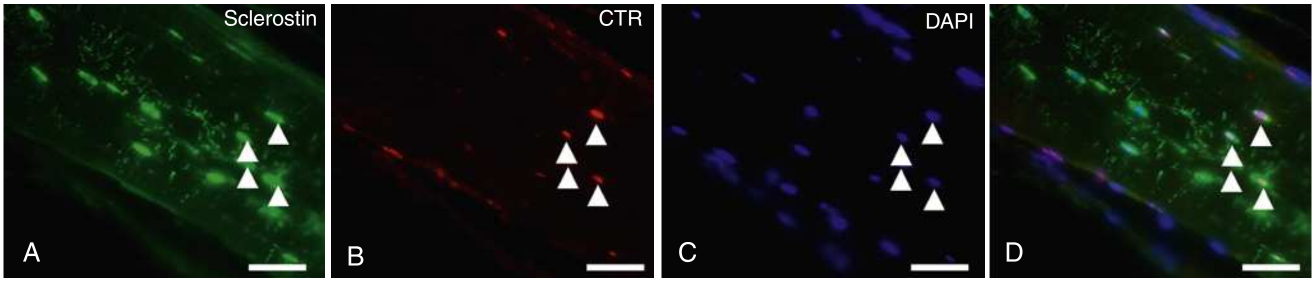

Fig. 49.5 Expression of calcitonin receptor (CTR) by mouse osteocytes. Immunohistochemical detection of CTR in osteocytes within young mouse calvariae. **A,** Green depicts sclerostin-positive osteocytes; **B,** red depicts CTR-positive osteocytes; **C,** blue depicts 4′,6-diamidino-2-phenylindole–stained nuclei in osteocytes; **D,** the merged image shows a subset of the sclerostin-positive osteocytes also positive for the CTR. (Used with permission from Gooi JH, Pompolo S, Karsdal MA, et al. Calcitonin impairs the anabolic effect of PTH in young rats and stimulates expression of sclerostin by osteocytes. *Bone.* 2010;46:1486–1497.)

been noted, including a transient increase in calcium excretion, probably caused by inhibition of renal tubular calcium reabsorption. Although this has not usually been regarded as an important effect of CT, it has been linked to the calcium-lowering effect of CT in hypercalcemic patients with metastatic bone disease. The use of CT in the treatment of hypercalcemia owing to cancer has been based exclusively on the inhibition of osteolysis by CT. However, there is evidence that failure of the kidneys to excrete the calcium load derived from bone breakdown is a major contributor to the hypercalcemia. This has prompted careful study of the relative contributions to the hypocalcemic effect of CT of its renal and skeletal components. It was concluded that inhibition of renal tubular reabsorption by CT can induce a rapid fall in serum calcium, and that the magnitude of this effect depends upon the correction of volume depletion that inevitably accompanies hypercalcemia.[110] In global CTR-deficient mice, hypercalcemia increased tubular reabsorption of calcium in the kidney,[61] whereas reabsorption was unchanged in mice in which *CTR* was deleted specifically in osteoclasts.[90] These data are consistent with the renal actions of CT to inhibit calcium reabsorption, to rapidly improve severe hypercalcemia, being mediated directly via the CTR. Thus, the calciuretic action of CT may assume greater importance than was hitherto suspected.

CTRs have been demonstrated in rat kidney,[116] and in humans the action of CT upon adenylate cyclase activity has been localized to the nephron, predominantly to the medullary and cortical portions of the thick ascending limb and to the early portion of the distal convoluted tubule. The colocalization of CTR mRNA expression and cell surface receptors with G protein–sensitive adenylate cyclase is consistent with cAMP being an important mediator of CT action in this organ. A possible role for CT in the kidney is to regulate $1,25(OH)_2D_3$ levels. The original observation was of enhanced 1-hydroxylation of 25(OH)D in the proximal straight tubule of the kidney by CT stimulation of the expression of the 25(OH)D 1α-hydroxylase.[117] Subsequently, Shinki et al.[118] showed that CT administration to rats induced renal CYP27B1 when serum calcium levels were normal or high, and this was supported by a report that CT treatment in rats increased renal production of *CYP27B1* mRNA.[119] CT stimulation of the expression of *CYP24* in CTR-transfected HEK-293 cells has also been reported.[120] The authors speculated that because $1,25(OH)_2D_3$ and CT synergistically stimulate *CYP24* mRNA production in kidney cells, this latter action of CT could be part of the process by which it regulates serum calcium, that is by controlling renal production of $1,25(OH)_2D_3$.

Calcitonin in the Central Nervous System

CTRs are widely distributed in the central nervous system.[39,40,121] Moreover, CT itself and immunoreactive CT-like peptides are produced in the central nervous system (CNS). Together, these findings suggest multiple autocrine or paracrine actions of CT and/or CT-related peptides in the brain, and effects on feeding,[122] pain sensation,[123] and regulation of pituitary prolactin secretion[124] have been documented. Intraventricular administration of CT generates potent effects that include analgesia and inhibition of appetite and gastric acid secretion, as well as modulation of hormone secretion and the extrapyramidal motor system.

Immunoreactive CT-like peptides have been demonstrated in the brain and nervous system of rats, humans, and other species.[27] Immunoreactive CT related antigenically to hCT (hCTI) has also been demonstrated in the nervous systems of protochordates, lizards, and pigeons, as well as at low levels in human and rat brain extracts. Low levels of hCTI also occur in extracts of postmortem human brain. However, in addition to hCTI, low levels of a molecular entity chromatographically and immunologically similar to sCT have been found, with concentrations in the brain approximately 10 times greater than those in serum and cerebrospinal fluid. Similarly, extracts of rat brain diencephalon contain an sCT-like peptide. Although hCTI has been detected in rat brain, only limited evidence has been found for the presence of rat CT mRNA.

Immunoreactive CT-like material also occurs in the pituitary of both mammals and lower vertebrates, and the CTR is present in the intermediate pituitary, at least in some species. CT has been described as participating in complex crosstalk between extracellular signaling molecules in the pituitary. For example, treatment of pituitary cells with CT in culture downmodulates the secretion of prolactin, whereas treatment of the cultures with an anti-CT antibody enhances it.[119] Accordingly, targeted overexpression of CT in gonadotrophs of mice leads to long-term hypoprolactinemia, decreased prolactin gene expression, female subfertility, and a selective underdevelopment of lactotrophs.

The complex effects of activating CTR in specific areas of the CNS linked to food intake are summarized elsewhere.[122] Overall, activation of the CTR by agonists in such areas leads to decreased food uptake. It has recently been demonstrated, for example, that the nucleus tractus solitarius (NTS) is crucial for integrating appetite, and that with ablation of CTR in the NTS, the long-term suppression of food intake was lost.[122] These results suggest a role for CTR in the regulation of energy balance.

The reported efficacy of CT in skeletal pain also appears to be mediated primarily in the CNS. Delivered either by injection or nasally, CT has been suggested as an adjunct treatment for acute, severe back pain secondary to fracture, as well as in Paget disease of bone and other painful conditions of the skeleton, such as osteoarthritis (see later), because of its analgesic properties. In a trial comparing elcatonin (a stabilized derivative of eel CT) with nonsteroidal anti-inflammatory (NSAID) medications for pain owing to vertebral fracture, elcatonin was reported to be more effective than NSAIDs.[123] The mechanism of CT-induced analgesia is not known, although several have been suggested, including increased secretion of β-endorphin from the pituitary gland, decreased synthesis of prostaglandins and other inflammatory factors, and modulation of serotonin transporter activity.[125]

KEY POINTS

- Calcitonin (CT) receptors are widely distributed in the brain, together with CT and CT-like peptides. This distribution is associated with multiple actions of CT and/or CT-related peptides in the brain, including effects on feeding, pain sensation, and regulation of pituitary prolactin secretion.

PEPTIDES RELATED TO CALCITONIN

CT is a member of a family of peptides, albeit with rather weak homology, that includes CGRP, AMY, CRSP, adrenomedullin (ADM), and IMD.[126] Greatest identity is between the teleost CTs and AMY (~33%). There is approximately 22% identity with the CGRPs and 16% identity with ADM. Even less homology is observed between the mammalian CTs and the other peptides. Consistent with the homology between peptides, there is a limited degree of overlap in specificity among the binding sites for the peptide receptors, with CT-like actions usually seen only at high concentrations of AMY and CGRP.

AMY is a 37–amino acid peptide that is cosecreted with insulin from pancreatic β cells following nutrient ingestion.[126] At physiological concentrations, AMY is important in the integrated control of nutrient influx, with potent actions that include inhibition of gastric emptying, gastric acid secretion, food intake, digestive enzyme secretion, and glucagon secretion. At higher concentrations, AMY also inhibits insulin secretion from the pancreas to promote glycogen breakdown and to decrease insulin-stimulated incorporation of glucose into glycogen in skeletal muscle. Thus, AMY is thought to act as a partner to insulin in metabolic regulation, although this effect may not occur at normal circulating levels of the peptide. In the kidney, AMY is proposed to have a diverse range of actions, including modulation of calcium excretion and thiazide receptor levels, proliferative effects on tubule epithelium, and increasing renin activity. *AMY*$^{-/-}$ mice have less bone, as the result of increased bone resorption, and *in vitro* tests indicated that this may be because of the release of an AMY-mediated attenuator of osteoclastogenesis. AMY receptors are widely expressed in brain, where administered peptide induces many potent effects. These include decreased appetite and gastric acid secretion, hyperthermia, adipsia, and reduction in growth hormone-releasing hormone. Central AMY injection may also modulate memory and the extrapyramidal motor system. The molecular nature of the AMY receptor is discussed later.

CGRP is a neuropeptide with a diverse range of actions, including potent dilation of vascular beds, as well as relaxation of other smooth muscle, inotropy and chronotropy in the heart, and paracrine regulation of pituitary hormone release, and many central effects, such as suppression of appetite and gastric acid secretion, modulation of body temperature, and modulation of sympathetic outflow. The actions of CGRP have been extensively reviewed elsewhere.[127] CGRP exists in two isoforms in humans: the main isoform present centrally is α-CGRP, whereas the β-CGRP isoform mainly functions in the periphery.[127] CGRP has been implicated in migraine, and a number of therapeutic agents have been trialed for efficacy in migraine treatment, including neutralizing CGRP antibodies and receptor antagonists. It was recently reported that salmon CT ameliorated migraine in a rat model by regulating central CGRP release from multiple cell types.[128]

ADM was originally isolated from human pheochromocytoma and is abundant in the normal adrenal medulla, hence its name. The full-length peptide of 52 amino acids shares approximately 25% homology with CGRP across its N-terminal 37 amino acids. ADM is a potent dilator of many vascular beds and is protective against conditions such as cardiac hypertrophy, perivascular fibrosis, renal damage, and pulmonary hypertension.[129]

As alluded to earlier, additional peptide members of the CT family have been identified. The CRSPs were originally identified from the porcine hypothalamus and being localized principally to brain and pituitary, have been proposed as potential endogenous ligands for central CTRs. However, not all CRSPs activate the CTR or related receptors, suggesting that they may also act at other receptors. A second ADM-like peptide (ADM 2 or IMD) has been identified in multiple species, including in humans. IMD can exert several actions similar to CGRP and ADM, including decreasing blood pressure, effects on cardiac function, and suppression of gastric emptying and food intake. IMD has also been found to cause renal effects similar to ADM. CRSP and IMD can inhibit bone resorption,[97] although their physiological actions remain to be identified.

CALCITONIN AND ITS RECEPTORS IN CANCER

Medullary Carcinoma of the Thyroid

The classic syndrome of CT excess is medullary carcinoma of the thyroid (MCT).[130] This tumor clearly differs in origin from all other thyroid cancers because it is a tumor of the CT-producing C cells. MCT may occur as a sporadic or a genetic (familial) tumor. The only effective treatment for MCT is surgical. The earlier this can be performed in the course of disease, the better the likelihood of a cure. Once the tumor becomes palpable, any treatment is unlikely to be curative. Because malignant C cells continue to produce CT, raised blood levels of CT provide an accurate diagnostic test for MCT, and continued raised levels after surgery suggest metastatic disease.[130] In rare cases, MCT is not accompanied by elevated serum CT. Genetic testing for the locus of mutation in the responsible gene (the *RET* protooncogene) often has considerable clinical relevance in management, as early surgery is key to survival, especially in the syndrome known as multiple endocrine neoplasia type 2b.

Calcitonin Receptors in Other Cancers

As stated, specific high-affinity receptors for CT have been demonstrated in human lymphoid cell lines, in a human lung cancer cell line, in several human breast cancer cell lines, including MCF-7, T47D, and ZR-75, in glioblastoma multiforme, and in PC cells. Indeed, CTR mRNA appears to be a frequent accompaniment of human tumors. The first clinical study of CTR in surgically obtained human breast cancers identified receptor mRNA production in all of 18 cancers, and receptor expression was confined to tumor cells in the sections.[131] In contrast, a subsequent study using laser capture microdissection and PCR found that the CTR in breast cancer tissue was actually reduced compared with adjacent normal breast tissue.[132]

The CT-CTR signaling pathway is implicated in human PC. Although CT is expressed endogenously in the prostate,[133] PCs display increased expression of CT and CTR compared with benign prostate tissue. Tumors with higher CT/CTR expression displayed metastatic disease and poor clinical outcome.[134] Forced expression of human CT in LNCaP human PC cells dramatically enhanced their oncogenic characteristics.[135] Moreover, CT promoted progression of PC cells from a localized cancer to an aggressive form by inducing a stem cell–like phenotype,[136] as well as increasing the concentration and activity of metalloproteinases that promote invasion, MMP-2 and MMP-9. A canonical

PDZ-binding site in the CTR cytoplasmic tail was shown to play a critical role in the CTR-mediated increase in invasiveness of PC cells and in the formation of distant metastases by orthotopically implanted PC cells in immunodeficient mice (Fig. 49.6).[137] Studies *in vitro* and *in vivo*, together with epidemiological data reporting an increased risk of cancer with CT use in osteoporosis patients, compared with those treated with bisphosphonates, prompted the European Medicines Agency to warn against the use of CT for this condition (see later).

KEY POINTS

- Calcitonin (CT) is important in a number of malignancies. The hallmark of medullary carcinoma of the thyroid is high circulating CT levels. The effects of CT on cell growth assume pathophysiological importance in some cancers, such as prostate cancer, with CT signaling inducing progression of primary tumors and metastatic invasiveness.

CALCITONIN AS A THERAPEUTIC

Hypercalcemia

CT has been used in the treatment of hypercalcemia in many different conditions, especially malignancy, but its effective use is limited by rapid tachyphylaxis, often within 24 hours of use. The development of resistance to this action of CT seems to involve downregulation of its receptor, which to some extent is blocked by corticosteroid use.[69]

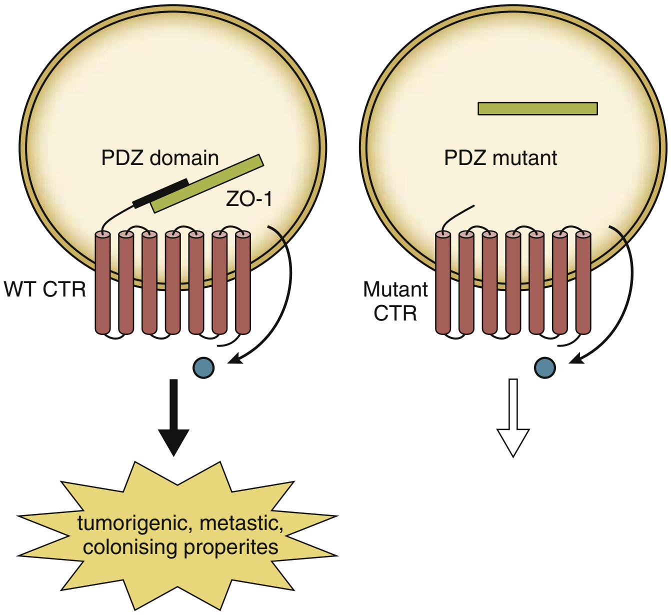

Fig. 49.6 **Calcitonin receptor (*CTR*)-mediated induction of stem-like cell phenotype of human prostate cancer (PC) cells.** Forced expression of wild type (*WT*) CTR in PC-3 and LNCaP PC-like cells induces tumorigenic, metastatic, and repopulation properties. CTR actions are dependent on the cytoplasmic tail PDZ domain, which interacts with the zonula occludens protein-1 (ZO-1). (From Chien J, Ren Y, Qing Wang Y, et al. Osteoporosis and Paget Disease of Bone

The antiresorptive action of CT has been the basis for its use clinically in osteoporosis, with an additional reported advantage being its analgesic effect on pain because of vertebral fracture.[138] CT treatment has modest effects on bone quantity (BMD) or bone remodeling markers, although there is reported improvement in bone quality parameters after administration of salmon CT nasal spray (CT-NS) over 2 years. The results of the QUEST study, in which effects of CT on bone structure were assessed by high-resolution magnetic resonance imaging (MRI), suggest therapeutic benefit of CT-NS compared with placebo in maintaining trabecular microarchitecture at multiple skeletal sites.[139] Similar protection by CT of bone structure was obtained in ovariectomized sheep, again with MRI used to assess bone changes. High doses of eel CT were effective in protecting bone architecture and strength in ovariectomized rats, and additional effectiveness was reported in combination with alendronate. A problem with CT use clinically has been its bioavailability, and to address this, both orally and nasally administered formulations of CT have been developed.[140]

CT given by subcutaneous injection was recognized as effective in the treatment of Paget disease, with relief of pain, return of biochemical indices of disease activity toward normal, formation of normal lamellar bone, and filling in of osteolytic lesions.[141] In long-term treatment of Paget disease with CT, the number of osteoclasts declines progressively, either because of a direct effect on osteoclast precursors or as an indirect consequence of the acute inhibition of osteoclast function by CT. With respect to an effect of CT on osteoclast development, it was reported that eel CT can protect from the bone loss of skeletal unloading by inhibiting the fusion of TRAP$^+$ mononuclear preosteoclasts.[142] This experiment was performed in 7-week-old mice, and its implications for adult humans are not clear. Skeletal blood flow (SBF) in normal male volunteers is approximately 5% of blood volume/min or about 4 mL/min/100 g of bone. In untreated Paget disease of bone, there is a striking increase in SBF at affected sites. Intriguingly, treatment with CT was shown to bring a rapid return to normal perfusion rates,[143] even before a detectable biochemical response. This response was similarly observed with bisphosphonate treatment and was postulated to explain the rapid pain relief obtained after commencement of treatment. The use of CT in Paget disease has been largely supplanted by bisphosphonates.

Osteoarthritis

A large number of *in vitro* and *in vivo* animal studies[144] have suggested the potential benefit of CT therapy in osteoarthritis. CT was found to attenuate indices of progression of osteoarthritis in several commonly affected joints[144] and to reduce the pain of osteoarthritis.[145] Studies designed to elucidate the mechanism of joint protection by CT found that it reduced IL1β-induced catabolism in chondrocyte cultures, as well as preventing cartilage degradation and subchondral bone changes in an *in vivo* rat model of osteoarthritis.[144] Potential benefits of CT have also been suggested for inflammatory arthritis, as it was found to preserve bone morphology in a rat model of rheumatoid arthritis, particularly when used with prednisolone. Thus a study in which CT and hyaluronic acid were formulated together in nanocomplexes and injected intraarticularly into the knee in a mouse model of inflammatory arthritis showed an apparently synergistic effect of the two agents in reducing markers of the disease.[146] Although studies such as those cited here claim that CT has direct effects on articular chondrocytes via the CTR, other investigators have been unable to find CTR expression or responsiveness to CT, at least in human chondrocytes.[147] The latter findings align with the difficulty of demonstrating a consistent effect of CT treatment on osteoarthritis in humans. Any benefits of CT in osteoarthritis could result from the effects of CT on subchondral bone, such as have been described for bisphosphonate treatment of animal models of osteoarthritis. However, like CT, these effects have been difficult to observe in human studies.

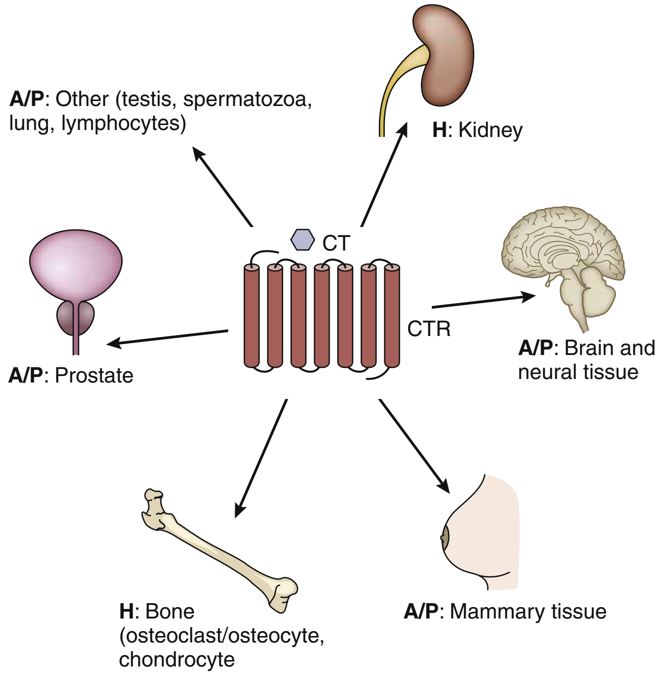
In 2012, the European Medicines Agency (EMA) recommended against the long-term therapeutic use of CT.[148] A possible causal link between long-term CT administration and the progression of PC was the given rationale for the recommendation. The EMA concluded that the benefit-risk balance remains positive only for treatment of Paget disease, immobilization-induced bone loss, and cancer-induced hypercalcemia in which patients cannot be treated with alternative agents. A similar recommendation was brought the following year by the US Food and Drug Administration, on the basis of a lack of benefit in the face of concerns about a cancer risk.[149]

KEY POINTS

- Calcitonin (CT) has been used in diseases of bone, primarily osteoporosis and Paget disease of bone, where its target is the inhibition of osteoclast resorption. The suggested and controversial efficacy of CT in osteoarthritis is now moot, given the recommendation by several drug regulatory agencies against its long-term therapeutic use.

CONCLUSION

A large number of actions and potential actions of CT have been discussed in this chapter (Fig 49.7), reflecting the wide tissue location of the CTR. Clearly, CT has both local paracrine actions and hormonal actions, and the significance of these appears to vary across life and is context-dependent, for example in reproduction, and sometimes species-specific. Although the clinical use of CT has declined in the last several decades, recent research has brought interesting discoveries that show the value of continuing to pursue the physiology and pathophysiology of this fascinating molecule.



A/P: Other (testis, spermatozoa, lung, lymphocytes)
H: Kidney
CT
CTR
A/P: Brain and neural tissue
A/P: Prostate
H: Bone (osteoclast/osteocyte, chondrocyte
A/P: Mammary tissue

Fig. 49.7 **Physiology of calcitonin (CT).** Cartoon shows putative target tissues of either hormonal (H) or autocrine/paracrine (A/P) CT or CT-like peptides acting at the CT receptor (CTR).

HISTORIC OVERVIEW

Early in the twentieth century, it was demonstrated that rachitic children were cured after exposure to sunlight or by oral cod liver oil. The new essential nutrient was called *vitamin D*. The two discoveries of vitamin D were unified by the demonstration that irradiation of 7-dehydrocholesterol in the skin could produce the antirachitic vitamin D. Irradiation of yeast ergosterol provided a large supply of vitamin D_2 used for the prevention and virtual elimination of vitamin D–deficiency rickets in the Western world (for references see Bouillon and Antonio[1]). During the last century, extensive studies revealed (1) the complex metabolism of vitamin D, which involves approximately 50 metabolites, (2) the mode of action of the most active metabolite, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), as a ligand for a specific and quite ubiquitous nuclear transcription factor, vitamin D receptor (VDR), and (3) the regulation of the expression of a very large number of genes (between 1% and 5% of the human genome) either involved in calcium homeostasis or related to a wide variety of functions in all vertebrates, including humans.

ORIGIN OF VITAMIN D: NUTRITION AND PHOTOSYNTHESIS

Vitamin D can be obtained from dietary sources of vegetal (vitamin D_2, or ergocalciferol) or animal (vitamin D_3, or cholecalciferol) origin. Approximately 70% of dietary vitamin D is absorbed by the enterocytes and transported to the blood circulation via chylomicrons. This vitamin D is taken up by a variety of tissues (fat and muscle) before the chylomicron remnants and their vitamin D finally reach the hepatocytes. The best food sources are oily fish, but it is also found in small amounts in butter, cream, and egg yolks. Breast milk (even from mothers living in equatorial areas of the world) and cow's milk are poor sources of vitamin D, providing only 15 to 40 IU/L, and only contain minimal concentrations of 25OHD or $1,25(OH)_2D$. In most countries, the median vitamin D intake is less than 5 μg/d, which is insufficient for daily needs. Therefore, many countries have introduced a policy of vitamin D enrichment of selected food items, such as fortification of milk and dairy products in North America, so that the median vitamin D intake according to National Health and Nutrition Examination Survey (NHANES) data is between 6 and 9 μg/d. Vitamin D is remarkably stable and does not deteriorate when food is heated or stored for long periods. In view of the low vitamin D content of a vegetarian diet (natural vitamin D intake is indeed related to intake of animal fat), vitamin D deficiency and rickets are risks for strictly vegetarian children with insufficient sun exposure or vitamin D supplementation. In view of the low contribution from food, most vitamin D comes from ultraviolet (UV) B –driven synthesis in the skin. The very same UVB light needed for the photochemical conversion of 7DHC to previtamin D is also able to damage DNA and causes photodamage, and, with a long lag time, increases the risk of skin cancers, including melanoma. This was no real problem during human evolution, but with increasing life expectancy the benefits of UV light for the photosynthesis of vitamin D should be compared with the lifetime risk of skin damage, especially as vitamin D supplementation can safely replace synthesis in the skin. As described in this chapter, and because of a combination of several predisposing factors, variable degrees of vitamin D deficiency are highly prevalent around the world. By contrast, excess vitamin D is quite exceptional.

Hypervitaminosis can occur when excess pharmaceutical vitamin D is taken, with a wide variety of symptoms and signs related to hypercalciuria, hypercalcemia, and ectopic calcifications (Table 50.1). The toxic dosage has not been established, but toxicity should always be monitored when daily doses that markedly exceed the current upper limit of

more than 100 µg are given for a long period of time. Overproduction of renal 1,25(OH)$_2$D by abnormal hormonal stimuli (as seen in fibroblast growth factor-23 [FGF-23] or Klotho-null mice) or absence of CYP24A1 (see later), the main catabolizing enzyme, causes the same calcemic side effects, with severe multiple-organ calcification (especially kidney, vascular wall, and heart valves) leading to premature death. Apart from hypercalcemic consequences, some randomized controlled trials (RCTs) suggest that serum concentrations above 45 ng/mL may have negative effects on the risk of falls or fractures (see later).

Apart from substrate (7DHC) availability (which may be influenced by genetic polymorphisms of 7HDC-Δ7-reductase enzyme), the photochemical synthesis of vitamin D$_3$ in the skin largely depends on the amount of UVB photons that strike the basal epidermal layers. Glass, sunscreen, clothes, and skin pigment absorb UVB and blunt vitamin D$_3$ synthesis. Latitude, time of day, and season are factors that influence the intensity of solar radiation and the cutaneous production of vitamin D$_3$. Therefore, there is a risk for a shortage of vitamin D supply during winter and spring. In both the Northern and Southern hemispheres above 40 degrees' latitude, vitamin D$_3$ synthesis in the skin decreases or disappears during winter months, owing to the low inclination of the sun and the atmospheric filtration of the shortest UV waves of sunlight, which are necessary for vitamin D$_3$ synthesis. The importance of skin synthesis of vitamin D$_3$ to maintain normal vitamin D status is best reflected by the high prevalence of vitamin D deficiency in countries where exposure to sunlight is extremely low for cultural and religious reasons. Solar exposure of 2 hours per week of the face and hands is probably enough for maintaining normal 25OHD concentrations in children and adults but should be further fine-tuned according to the climate and latitude. There is no unanimity regarding the amount of vitamin D produced by UVB exposure, as older studies suggested that full-body exposure to UVB may produce more than 20,000 IU/d, whereas more recent studies of young adults exposed to intensive sun exposure during a winter holiday in the Canary Islands showed an increase in serum 25OHD equivalent to the daily supply of approximately 800 IU/d (for references see[2]).

Nature has built in several feedback mechanisms to minimize the risk of prolonged sun exposure causing vitamin D intoxication. Cutaneous vitamin D, and especially previtamin D, are photosensitive and are degraded to inactive sterols. Sunlight-induced melanin synthesis, acting as a natural sunscreen, provides additional negative feedback. This is best demonstrated by mean serum 25OHD levels of approximately 45 ng/mL found in Masai and other African tribes with extensive exposure to sunlight. These values are higher than mean values found in most other populations but lower than expected on the basis of intensive UVB exposure and skin capacity to produce vitamin D.

KEY POINTS

- Intake of vitamin D from food is low because most food items have a low vitamin D content and is insufficient for most people.
- Most vitamin D is synthesized in the skin after exposure to ultraviolet B sun rays. Unfortunately, these ultraviolet B rays are also photodamaging to the skin and can increase the risk of skin cancer in the long term.
- The vitamin D content of breast milk is low and largely insufficient to cover the needs of infants or children around the world.
- Vitamin D excess attributed to overexposure to sunlight is highly unlikely because evolution has provided many mechanisms to avoid vitamin D toxicity.

METABOLISM OF VITAMIN D

Vitamin D is biologically inert and requires two successive hydroxylations in the liver (on C$_{25}$) and kidney (on the α position of C$_1$), mediated by cytochrome P450 enzymes to form its hormonally active metabolite, 1,25(OH)$_2$D (Fig. 50.1).

25-Hydroxylation

Although the liver is probably the main tissue responsible for 25-hydroxylation of vitamin D, extrahepatic 25-hydroxylation has been observed in many tissues. The most important 25-hydroxylase is CYP2R1 because biallelic mutations of the gene encoding this protein were identified in patients with classical rickets with low 25OHD levels. Several other cytochrome P enzymes are, however, also able to perform the same reaction. In contrast to the widespread concept of constitutive *CYP2R1* expression, new data in mice have demonstrated that this gene is controlled by several metabolic conditions, as both gene and protein expression are strongly reduced in cases of fasting, diet-induced obesity, glucocorticoid exposure, or type 1 diabetes mellitus (T1DM) or type 2 diabetes mellitus (T2DM). PPAR gamma coactivator, estrogen-related receptor, and glucocorticoid receptor are all involved in the regulation of *Cyp2r1* in mice. If this also applies to humans, it may well help to explain the frequent association between low serum concentrations of 25OHD and many metabolic diseases (reviewed in Bouillon & Bikle[3]).

1α-Hydroxylation

25OHD is biologically inactive and requires further hydroxylation in the kidney to the active hormone, 1,25(OH)$_2$D, by 25-hydroxyvitamin D-1α-hydroxylase (CYP27B1). The production of 1,25(OH)$_2$D is regulated primarily at this final step by several factors. The proximal renal tubule is the principle site of 1α-hydroxylation, but high levels of CYP27B1 mRNA and enzyme activity have also been found in human keratinocytes, macrophages, and approximately ten other tissues. Renal CYP27B1 activity is tightly controlled by 1,25(OH)$_2$D (negative feedback), by parathyroid hormone (PTH), calcitonin, and insulin-like growth factor 1 (all positive feedback), as well as by phosphate, calcium, and especially FGF-23 (negative regulation). The promoters of the mouse and human *CYP27B1* genes are profoundly responsive to PTH and are negatively regulated by 1,25(OH)$_2$D.[4] Extrarenal CYP27B1 activity is regulated by different (yet to be identified) mechanisms in the skin and monocytes.

Pseudovitamin D–deficiency rickets, also known as vitamin D–dependency rickets type I, is an autosomal recessive disease characterized by failure to thrive, muscle weakness, skeletal deformities, hypocalcemia, secondary hyperparathyroidism, normal to high serum levels of 25OHD, and low serum 1,25(OH)$_2$D concentrations, all caused by impaired activity of renal CYP27B1. These patients recover well when treated with oral physiologic doses of 1,25(OH)$_2$D.[2,5,6]

Fig. 50.1 Major enzymes and metabolic pathways of vitamin D. Vitamin D_3 originates from dietary sources or is synthesized in the skin from 7-dehydrocholesterol into previtamin D. Approximately one in three molecules of vitamin D is later found as 25OHD generated by CYP2R1 (mostly in the liver) and maybe to a lesser extent by some other cytochrome P enzymes. What happens to the other vitamin D molecules is not fully known (they may be esterified or metabolized into other D metabolites by CYP11A1). In normal subjects approximately one molecule of 25OHD is metabolized into $1,25(OH)_2D$ by CYP27B1 in the kidney under tight feedback control. The major $1,25(OH)_2D$ catabolic pathways are under the control of a multifunctional CYP24A1 that generates many intermediate metabolites, ultimately generating calcitriol or lactones. The role of several epimerases is unknown, and their endproducts are so far believed to be largely devoid of physiologic action. CYP3A4 probably has a minor role, except in case of drug-induced induction of this enzyme, in which case it accelerates 25OHD degradation. *DBP,* Vitamin D–binding protein; *GC*, group-specific component; *UV*, ultraviolet.

24-Hydroxylation: Catabolism or Specific Function?

An alternative hydroxylation of 25OHD occurs on carbon 24 mediated by the multifunctional enzyme 24-hydroxylase (CYP24A1). This enzyme not only initiates the catabolic cascade of 25OHD and $1,25(OH)_2D$ by 24-hydroxylation but catalyzes its further metabolism into calcitroic acid. Evidence for this catabolic role of 24-hydroxylase was provided by *Cyp24a1*-deficient mice, which exhibited pathology consistent with systemic excess of $1,25(OH)_2D$. Expression of the *CYP24A1* gene has been detected in virtually all nucleated cells. Induction of *CYP24A1* expression is a highly sensitive biomarker for responsiveness to vitamin D supplementation owing to the presence of several vitamin D–responsive elements in its promoter. Several mutations in the human *CYP24A1* gene have recently been found to be responsible for infantile hypercalcemia and increased risk of kidney stones in adults.[7]

Patients with loss-of-function *CYP24A1* mutations have been successfully treated by restriction of vitamin D intake or with inhibitors of vitamin D synthesis or inducers of *CYP3A4* expression.

KEY POINTS

- Vitamin D is an inactive precursor and requires hydroxylation by CYP2R1 to produce 25-hydroxyvitamin D (the main circulating metabolite) and by CYP27B1 to produce 1,25-dihydroxyvitamin D [1,25(OH)2D]. The catabolism of all vitamin D metabolites largely depends on CYP24A1. Genetic or acquired deficiency of each of these enzymes can generate important diseases related to disruption of calcium, phosphate, or bone homeostasis. There are, however, several other metabolic steps resulting in approximately 50 different (probably mostly inactive) metabolites.

Other Metabolic Pathways for Vitamin D and its Metabolites

Apart from the multifunctional 24-hydroxylation pathway, C_{23} and C_{26} hydroxylation of $1,25(OH)_2D$ are also possible in the absence of prior 24-hydroxylation. Both activities are necessary for the formation of 25OHD- or $1,25(OH)_2D$-23,26-lactones. A-ring metabolism involves C_{19} oxidation and 3-epimerisation. The latter reaction, which is irreversible, occurs only in a limited number of cells (e.g., keratinocytes, bone, and parathyroid cells) and is performed by hydroxysteroid dehydrogenases. 1-epi-25$(OH)_2D$ also circulates in the serum and exhibits a strong correlation with serum 25OHD concentrations. The enzyme or tissue responsible for its synthesis, and the implications, are still to be explored.[8]

The physiologic implications of 4-hydroxylation or 11-hydroxylation are presently unclear. CYP3A4 is another P450 enzyme with mainly a detoxicating function but can also strongly influence vitamin D metabolism. Excess activity (owing to either genetic mutation or drug-induced induction of this enzyme) increases vitamin D/25OHD catabolism, and can even lead to rickets (type 3)[9] (for a review see Bouillon and Bikle[3]) (Fig. 50.1). Vitamin D is mainly excreted in the bile after esterification in the liver, but some of its more polar metabolites (e.g., calcitroic acid) are excreted via the urine. The enterohepatic recirculation of vitamin D esters is probably devoid of biological relevance.

VITAMIN D TRANSPORT

Nutritional vitamin D is absorbed by the gut and then transported via the lymphatic system by chylomicrons and stored in several tissues (e.g., fat and muscle). Skin-produced vitamin D binds directly to an α-globulin known as vitamin D–binding protein (DBP). This protein is essential for transport to the liver, where vitamin D is hydroxylated and thereafter released as 25OHD, again bound to DBP. Human DBP, also known as group-specific component, or GC-globulin, is a highly polymorphic glycoprotein synthesized by the liver. Worldwide, over 120 *GC* alleles have been detected, making the *DBP* locus one of the most polymorphic known. *GC1F*, *GC1S*, and *GC2* are the three most common alleles.[10]

Dbp-null mice are viable and fertile and have a normal bone and calcium homeostasis, despite extremely low concentrations of 25OHD and 1,25$(OH)_2D$. This is a very strong argument in favor of the role of free rather than total concentrations because tissue samples from these mice show normal free 1,25$(OH)_2D$ concentrations. One only case of biallelic mutations with silencing of *DBP* has been described. This adult woman did not have vitamin D–related health problems, despite near-undetectable serum concentrations of all vitamin D metabolites.[11] DBP has a cleft on its surface that serves as a binding site for all vitamin D metabolites. Its affinity for D_2 metabolites is slightly lower than that for D_3 metabolites. As probably only non–DBP-bound vitamin D metabolites can readily cross the plasma membrane, and given that the VDR has a much higher affinity for 1,25$(OH)_2D$ than for 25OHD (100-fold difference), while the opposite is true for DBP, it is clear that 1,25$(OH)_2D$ has substantially higher cellular uptake than 25OHD. The half-lives of 25OHD and 1,25$(OH)_2D$ in the human circulation are approximately 2 weeks and 4 to 6 hours, respectively.[12] DBP's function in the vitamin D endocrine system is assumed to reflect the "free hormone" hypothesis, which states that the unbound (free), rather than the protein-bound, fraction of the active vitamin D hormone is responsible for its biological activity. The plasma concentration of DBP is increased by estrogens. In women, the DBP concentration therefore doubles at the end of pregnancy. Studies with *Megalin*-null mice indicate that megalin, a lipoprotein-like receptor present at the surface of the proximal tubular cells in the kidney, is responsible for the reabsorption of DBP and of DBP complexed with vitamin D sterols. This megalin reabsorption mechanism may control the availability of the 25OHD/DBP complex for the 25OHD-1α-hydroxylation enzyme and explain the severe bone disease of *Megalin*-deficient mice. *Dbp*-null mice are more sensitive to vitamin D deficiency and less sensitive to vitamin D excess, probably because of enhanced urinary loss of vitamin D metabolites.[10] The *Dbp* and *Megalin* null mice suggest that the main function of DBP is indeed to transport all vitamin D metabolites and preserve them from rapid clearance or urinary loss.

DBP binds globular actin with a high affinity ($K_a = 2 \times 10^9$ mmol/L). Actin is the most abundant intracellular protein. Cell motility, shape, and size depend on the ability of globular actin to polymerize into filaments (F-actin). Upon cell injury or cell necrosis, actin is released into the extracellular space. When actin is released from cells, it may rapidly form filaments, with detrimental effects for the microcirculation. Two plasma proteins, DBP and gelsolin, bind actin avidly, thereby acting as an "actin-scavenger" system.[10] Whether this has clinical implications for human health and disease is so far unknown.

KEY POINTS

- All vitamin D metabolites are bound in serum to a specific vitamin D–binding protein, DBP, the oldest member of the albumin family. Absence of DBP does not cause a clinical phenotype, but serum concentrations of all vitamin D metabolites are extremely low. This confirms that the free vitamin D hormone concentration is physiologically important.

ACTION AND MODE OF ACTION

General Characteristics of the Vitamin D Receptor

1,25$(OH)_2D$, the hormonally active form of vitamin D, exerts its effects mainly by activating the nuclear VDR, a member of the nuclear-receptor superfamily of ligand-activated transcription factors that has a structure similar to that of other steroid-binding nuclear receptors.[10,13] The human *VDR* gene on chromosome 12 encodes a 427–amino acid protein, with some minor variants containing an additional 23 or 50 amino acids at the N-terminus.

Genomic Actions. Binding of 1,25$(OH)_2D$ to VDR generates conformational changes in VDR followed by heterodimerization with unliganded RXR and binding to vitamin D response elements (VDREs) in the promoter region of vitamin D target genes, with subsequent release of corepressors and recruitment of coactivators and general transcription factors for the assembly of an active transcriptional complex. A crucial event in this respect is the mousetrap-like intramolecular folding of helix 12, which closes off the ligand-binding pocket and exposes the activation function domain for interaction with coactivators. Corepressors bind and silence unliganded steroid receptors via recruitment of histone deacetylases, maintaining chromatin in a transcriptionally repressed state. Coactivators are a group of proteins that allow gene transcription in several waves of activity. Gene expression can also be mediated by adenosine triphosphate (ATP)-dependent chromatin remodeling complexes such as SWI/SNF-type and ISWI-type complexes and the multiprotein complex WINAC. Furthermore, the expression or the recruitment of these regulatory proteins is regulated by several intracellular signaling pathways and by steroids themselves, with receptor agonists or antagonists inducing preferential recruitment of coactivators or corepressors, respectively. Finally, 1,25$(OH)_2D$ also controls gene regulation by regulating several miRNAs. A hexanucleotide direct repeat spaced by three nucleotides is the cognate VDRE of which RXR and VDR bind the 5′ and 3′ ends, respectively, although alternative options appear to be possible.

Nongenomic Actions. Several groups have described rapid effects of 1,25$(OH)_2D$ that are independent of transcription and are mediated by a membrane receptor for 1,25$(OH)_2D$. These so-called nongenomic effects are also well known for other nuclear receptor ligands such as estradiol or progesterone and include the opening of calcium or chloride channels and the activation of second-messenger signaling pathways. The *in vivo* effects of these nongenomic actions remain unexplained.

Classic Target Tissues

The action of 1,25$(OH)_2$D on bone, intestine, kidney, and the parathyroid glands and its role in mineral metabolism is the result of a complex interplay between calcium and phosphate, 1,25$(OH)_2$D, PTH, and phosphatonins.[14] PTH induces calcium mobilization from bone and stimulates 1,25$(OH)_2$D production, but its secretion is inhibited by the action of 1,25$(OH)_2$D on the parathyroid glands (negative feedback). In a second negative feedback loop, 1,25$(OH)_2$D limits its own availability by inhibition of CYP27B1 and stimulation of CYP24A1, inducing 1,25$(OH)_2$D catabolism. In the last few years, considerable progress has been made in understanding phosphate homeostasis. The phosphaturic hormone phosphatonin, or FGF-23, is produced by osteocytes and osteoblasts and inhibits the activity of the NPT2 protein. The *NPT2* gene encodes a renal sodium/phosphate cotransporter responsible for reabsorption of phosphate and represents a newly identified target gene for 1,25$(OH)_2$D. Phosphatonin can be indirectly inactivated by a protease encoded by the *PHEX* gene, which was identified as the gene that is defective in X-linked hypophosphatemic rickets. FGF-23 secretion is stimulated by 1,25$(OH)_2$D and impairs renal CYP27B1, creating an additional feedback system, such that the production of 1,25$(OH)_2$D is tightly feedback-regulated.

Effects on Intestine. The efficiency of the small intestine to absorb dietary calcium is increased by 1,25$(OH)_2$D, and VDR abundance is highest in the duodenum, followed by the jejunum and the ileum. Although the exact mechanism by which 1,25$(OH)_2$D alters the flux of calcium across the intestinal absorptive cell is not known, 1,25$(OH)_2$D increases the production and activity of several proteins in the small intestine, including transient receptor potential cation channel subfamily V (TRPV) member 6 (TRPV6) and TRPV5, calbindin-D9K, alkaline phosphatase, and low-affinity Ca-ATPase (PMCA). The entry of calcium from the intestinal lumen across the brush border membrane into the enterocyte is mainly regulated by the epithelial channels TRPV6 and TRPV5. The intracellular calcium transfer is considered to be dependent mainly on calbindin-D9K. The transfer of calcium from the cytoplasm to the extracellular space requires energy input because of an uphill concentration gradient and an unfavorable electrochemical gradient. Both the plasma membrane calcium pump and a sodium-calcium exchanger play important roles in this process. The stimulatory effect of 1,25$(OH)_2$D on the ATP-dependent uptake of calcium at the basolateral membrane involves an increase in *PMCA* expression. The essential role of the intestine for calcium and phosphate homeostasis was clearly demonstrated by the phenotype of *Vdr* knockout mice. Such *Vdr*-null mice are phenotypically normal at birth, but after weaning they develop hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia, despite very high levels of 1,25$(OH)_2$D. They become growth-retarded and develop severe rickets. Mice deficient in *Cyp27b1* display a similar phenotype.[5,13] This bone and calcium phenotype can be largely corrected by a high dietary calcium intake (especially in combination with high lactose intake) in both knockout models or by 1,25$(OH)_2$D treatment in *Cyp27b1*-null mice. These findings confirm previous observations in humans. These data strongly suggest that the intestine is the primary target for 1,25$(OH)_2$D's action on calcium/bone homeostasis. This is largely confirmed by genetic mouse models of selective rescue or deletion of *Vdr* in the intestine of transgenic mice.[15] The primary molecular targets, however, merit further exploration; mice with ablation of *CaBP-9k* or *TRPV6*, or even both, can still partially increase their intestinal calcium absorption, and serum calcium levels are normal. Paracellular intestinal calcium transport may also be part of the picture of vitamin D's action, in that the expression of claudin 2 and claudin 12, both known to form paracellular calcium channels, is induced by 1,25$(OH)_2$D and decreased in the intestine of *Vdr*-null mice.[5]

Effects on Kidney. The kidney is important both for the metabolism of 1,25$(OH)_2$D and the reabsorption of calcium and phosphate, all processes that are regulated by 1,25$(OH)_2$D.[5] The kidney, and more specifically the proximal tubule, is the central tissue for 1α-hydroxylation of 25OHD. Chronic renal failure reduces CYP27B1 activity, which ultimately results in renal osteodystrophy or uremic bone disease. 1,25$(OH)_2$D also increased the distal tubular reabsorption of calcium; as in the intestine, TRP channels (especially TRPV5), calbindin-D9K and -28K, and the plasma membrane calcium ATPase are involved. The crucial role of 1,25$(OH)_2$D-regulated renal calcium reabsorption was demonstrated by persistent hypercalciuria and reduction in bone mass in TRPV5-deficient mice. The kidney is also the major component in phosphate homeostasis, as both PTH and FGF-23, in complex interplay with 1,25$(OH)_2$D, are able to reduce renal phosphate reabsorption

Effects on Bone. 1,25$(OH)_2$D has dual effects on bone: it can stimulate osteoclastogenesis and bone resorption, as well as modify osteoblast function and bone mineralization. The overall effects of vitamin D metabolites on bone are thus extremely complex. From observations in humans and animals, vitamin D deficiency or resistance impairs bone matrix mineralization, whereas osteoblast activity and matrix synthesis are even stimulated. Excess 1,25$(OH)_2$D can clearly enhance osteoclastogenesis and bone resorption. Because bone mineralization and bone structure can be largely normalized in vitamin D- or 1,25$(OH)_2$D-deficient or resistant mice by sufficient supply of minerals via active or passive intestinal calcium absorption, it seems that the direct effects of vitamin D metabolites on chondrocytes and bone cells are redundant if calcium and phosphate supply are guaranteed. However, most of the genes and proteins typically expressed in osteoblasts and osteoclasts are vitamin D–regulated, so it is likely that 1,25$(OH)_2$D can fine-tune bone mineral homeostasis.

The direct effects of the vitamin D endocrine system on bone cells are slowly being unraveled by studies employing cell–specific *Vdr* deletion: *Vdr* deficiency in osteoblasts modestly increases bone mineral mass, whereas *Vdr* deficiency in osteocytes does not affect basal bone mass or structure.[15] However, mice with osteocyte-selective *Vdr* deficiency exposed to a very low calcium diet or high 1,25$(OH)_2$D concentrations are protected against 1,25$(OH)_2$D-induced bone loss.[15] This is largely owing to 1,25$(OH)_2$D-mediated inhibition of mineral deposition (creating instead of solving osteomalacia) by regulating several genes (*ANK*, *ENPP1&3*, *TNAP*) as to increase PPi and other mineralization inhibitors such as osteopontin and other SIBLING proteins.[15] Therefore, it seems that 1,25$(OH)_2$D can have different effects on bone: in cases of sufficient calcium intake, it helps to stimulate calcium absorption and provide minerals and osteoblast function so as to improve mineral deposition; however, in cases of calcium deficiency, 1,25$(OH)_2$D will primarily defend serum calcium homeostasis at the expense of bone (increased bone resorption and inhibition of mineral deposition). This should not be a major surprise, as the vitamin D endocrine system, together with PTH, evolved during vertebrate evolution as to enable terrestrial animals to cope with increased gravity (necessitating a solid bone structure) while living in a calcium-poor environment.

Effects on Growth Plate. The absence of *Vdr* or *Cyp27b1* creates no detectable phenotype in overall growth or growth plate of prenatal animals, but the longitudinal growth of long bones is impaired after weaning. X-ray analysis reveals advanced rickets, including widening of the epiphyseal growth plate, with an increased width and marked disorganization of the growth plate on histology, including impaired mineralization of hypertrophic chondrocytes. This increased growth plate width in *Vdr*- or *Cyp27b1*-null mice is not caused by abnormal chondrocyte proliferation or differentiation, and the expression of major proteins such as collagen X and osteopontin is normal. The expansion of the growth plate can be largely explained by decreased apoptosis of hypertrophic chondrocytes. Based on analysis of several genetic models with abnormal phosphate homeostasis, serum phosphate levels are probably crucial for hypertrophic chondrocyte apoptosis *in vivo*. This is confirmed *in vitro*: apoptosis of hypertrophic chondrocytes is regulated by phosphate levels via the activation of the caspase-9–mediated mitochondrial pathway. In accordance with these findings, chondrocyte-specific inactivation of *Vdr* did not cause a growth plate phenotype, and certainly not rickets.

Parathyroid Glands. The parathyroid gland is an important target for vitamin D action, as it regulates the sensing of serum ionized calcium through a G-protein–coupled calcium-sensing receptor. Several parathyroid genes, including *CaSR* and *PTH*, are under the control of 1,25$(OH)_2$D. Tissue-selective knockout of *Vdr* in the parathyroid gland causes hyperparathyroidism and increased bone turnover. Parathyroid-selective deletion of *Cyp27b1* creates a complex mixture of hypocalcemia, low serum 1,25$(OH)_2$D levels and decreased bone mass, thus questioning the unique role of the kidney in the production of systemic 1,25$(OH)_2$D. The vitamin D endocrine system also plays a key role in the genesis of secondary hyperparathyroidism of chronic renal failure, including the suppression of local CYP27B1 activity by excess FGF-23.

KEY POINTS

- 1,25(OH)2D binds to a specific nuclear receptor, the vitamin D–binding receptor (VDR), and this complex recruits a set of other proteins that together regulates gene transcription, very similar to the mode of action of many other hormones that bind to nuclear receptors.
- The most important target tissue of 1,25(OH)2D is the intestine, as it stimulates the expression of several calcium-binding proteins that, combined, are responsible for intestinal calcium absorption. VDR is also expressed in all bone cells, but the direct effects of 1,25(OH)2D on these bone cells or chondrocytes are limited.
- VDR is expressed in many nonskeletal cells and regulates a very large number of genes (up to 5% of the human genome) that are unrelated to calcium or phosphate handling, and are mostly regulated in a coherent fashion. This suggest that the vitamin D endocrine system may have a wide spectrum of biological activities.

CLINICAL CONSEQUENCES OF VITAMIN D STATUS

Skeletal Effects of the Vitamin D Endocrine System

The absence of vitamin D, its active metabolite, 1,25$(OH)_2$D, or its receptor causes rickets in children and osteomalacia in adults. Nutritional rickets is mostly caused by poor vitamin D status, especially during rapid growth. In some areas of the world a poor calcium intake generates a very similar picture of rickets. Apart from nutritional rickets, genetic defects in vitamin D metabolism or action, genetic or acquired defects in phosphate homeostasis resulting in hypophosphatemia, or a series of genetic defects involved in mineral deposition (such as deficiency of alkaline phosphatase or excess pyrophosphate) are rare causes of rickets.[16] Nutritional rickets can be effectively prevented by appropriate vitamin D and calcium intake. However, nutritional rickets is still frequent in many countries or in high-risk groups.[1,17] There is fairly general consensus on how rickets could be eradicated, as daily supplementation with 400 IU of vitamin D (usually D_3) has been proven to eradicate rickets in countries with a systematic supplementation policy (reviewed in Bouillon & Antonio[1]). The minimal calcium requirements are age-dependent and well described in a consensus document.[18] The implementation of an adequate strategy is still poor or slow, and a dedicated program led by scientists, healthcare policy makers, and especially the World Health Organization (WHO), United Nations Children's Emergency Fund, and major charities is long overdue.[1,18,19] A less well-recognized consequence of vitamin D deficiency early in life deals with teeth development. Impaired mineralization of dentin in postnatal life results in tooth decay or tooth loss. As enamel, the hardest tissue of the body, is already deposited during late pregnancy, improvement of vitamin D status in the perinatal period may improve tooth (enamel and dentin) development, with permanent consequences for tooth health. There is much more debate on the role of vitamin D status on bone density and risks of fracture in postmenopausal or elderly subjects. A very large number of RCTs did not find a beneficial effect of calcium supplementation on fractures. Similarly, supplementation with vitamin D alone did not reduce fracture risk. In a highly publicized paper published in *Lancet Diabetes Endocrinology* in 2018,[20] the authors concluded that "there is little justification to use vitamin D supplements to maintain or improve musculoskeletal health." In their metaanalysis of 81 RCTs ($n = 53{,}537$ participants) that reported data on fracture ($n = 42$), falls ($n = 37$), or bone mineral density (BMD) ($n = 41$), vitamin D supplementation had no effect on (1) total fracture (36 trials; $n = 44{,}790$, relative risk [RR] 1.00, 95% confidence interval [CI]: 0.93–1.07), (2) hip fracture (20 trials; $n = 36{,}655$, RR 1.11, 95% CI: 0.97–1.26), or (3) falls (37 trials; $n = 34{,}144$, RR 0.97, 05% CI: 0.93–1.02). Results were similar in RCTs of high-dose versus low-dose vitamin D. However, the majority of the included studies lasted less than 12 months (and thus were unable to evaluate fracture outcome), the metaanalysis included two studies using very high bolus doses of vitamin D known to transiently increase fractures or falls, and a very large number of studies were performed in subjects with adequate vitamin D status at baseline. Above all, the authors deliberately did not include studies dealing with combined treatment with vitamin D and calcium supplements versus double placebo. However, in 2014 one of the authors reported[21] that vitamin D plus calcium versus placebo or no treatment resulted in a statistically significant reduction in (1) risk of hip fracture (9 trials; $n = 49{,}853$; RR 0.84; 95% CI: 0.74–0.96), (2) incidence of new nonvertebral fractures (8 trials; $n = 10{,}380$; RR 0.86; 95% CI: 0.78–0.96), and (3) incidence of any fracture (10 trials; $n = 49{,}976$; RR 0.95; 95% CI: 0.9–0.99). In addition, one of the other authors of the *Lancet Diabetes Endocrinology* paper concluded independently[22] that vitamin D plus calcium reduced hip fracture in institutionalized individuals (2 trials; $n = 3{,}853$) but did not reduce the risk of hip fracture by 15% or more in community-dwelling individuals (7 trials; $n = 46{,}237$). However, older studies, mostly performed in elderly women with rather poor vitamin D status and lower than optimal calcium intake, demonstrated that vitamin D supplementation alone did not reduce fracture risks, but that a combination of vitamin D and calcium supplementation reduced the risk of hip or nonvertebral fractures by 10% to 20% (reviewed in Weaver et al.[23] and Bouillon & Bikle[2]). The recent VITamin D and OmegA-3 TriaL (VITAL)[24] and the Vitamin

D Assessment Study (ViDA)[25,26] did not find beneficial effects on fractures, but these studies mostly included vitamin D–replete adults with generally good calcium intake. In a subanalysis, BMD increased in both studies relative to the placebo group in subjects with low total or free 25OHD. The Calgary study intended to explore the effects and safety of daily high-dose vitamin D (4000 and 10,000 IU vs. 400 IU) for 3 years on bone structure and quality (measured by high resolution peripheral quantitative computed tomography [HRpQCT]) in 311 Canadian adults.[27,28] Surprisingly, BMD at the radius and tibia decreased by 3.5% and 1.7%, respectively, in the 10,000 IU/d group, whereas the decrease at both sites was nonsignificantly lower in the 4000 IU/d group compared with the 400 IU/d group. This study does demonstrate that vitamin D supplementation of vitamin D–replete adults (baseline serum 25OHD of ~30 ng/mL) does not improve bone quality or quality. Moreover, very high doses may even have negative effects, as a small percentage of subjects developed hypercalciuria or hypercalcemia that quickly resolved after adjustment of dosing. Of course, this may imply that regular follow-up is desirable when using such dosages.[27,29]

The interpretation of older and newer data suggests that:

1. Vitamin D supplementation of subjects with a poor vitamin D status at baseline (<12–20 ng/mL) reduces the age-related loss of bone density.
2. Combined correction of poor vitamin D status and low calcium intake is recommended by most international guidelines, especially for the elderly population, and seems to be able to modestly reduce the risk of fracture. Most guidelines recommend a daily dose of 800 IU of vitamin D_3. The European Calcified Tissue society also recently supported this conclusion.[30]
3. Vitamin D supplementation (equivalent to 2000–3000 IU/d) given to vitamin D–replete adults does not generate additional bone health benefits.
4. High pulse doses of vitamin D (>300,000 IU) should be avoided because they may be associated with transient increased risk of fracture.[31]
5. Based on the results from the Calgary studies,[27,28] high daily doses (4000–10,000 IU) of vitamin D may result in increased urinary calcium excretion and sometimes even hypercalcemia, whereas BMD, as measured by the highly sensitive HRpQCT method may even decrease, rather than improve.
6. As most trials with active osteoporosis drugs (antiresorptive and others) added a calcium and vitamin D supplement in the active and control groups, the logic of evidence-based medicine requires that the active drug should be given to subjects with a good vitamin D and calcium status, and in the majority of cases this will require a daily supplement.

KEY POINTS

- Absence of vitamin D, its active metabolite 1,25(OH)2D, or vitamin D receptor causes rickets in infants or children, characterized by excess unmineralized bone (osteoid), too little solid mineralized bone, and an extremely delayed mineralization rate. Nutritional rickets is either as a result of too little vitamin D or too little calcium intake/absorption and can/must be prevented by appropriate access to vitamin D (~400 IU or 10 ug/d) and calcium (age-dependent). Unfortunately, nutritional rickets is still endemic in some parts of the world and in specific risk groups. Severe vitamin D deficiency in adults causes osteomalacia.
- A poor vitamin D status in elderly subjects may accelerate osteoporosis, whereas adequate vitamin D and calcium intake can modestly reduce the risk of osteoporotic fractures.

Extraskeletal Actions of the Vitamin D Endocrine System

The virtually ubiquitous expression of VDR in all nucleated cells, the presence of a functional CYP27B1 in at least 10 different tissues apart from the kidney, and the very large number of genes that are under direct or indirect control of $1,25(OH)_2D$ (even early in the evolution of vertebrates, as observed in zebrafish) all point toward a more universal role for the vitamin D endocrine system than just regulation of calcium/phosphate/bone metabolism. This is not totally unexpected, as most other nuclear receptor ligands, such as androgens, estrogens, glucocorticoids, and retinoids, also have a very wide spectrum of activities. Based on a massive number of observations in cells, tissues, and transgenic mice it seems likely that the total absence of vitamin D action may have many extraskeletal effects. This is in line with many observational studies in humans, but the final proof of causality requires data from Mendelian randomization (MR) or RCTs. Large-scale genetic testing has identified several polymorphisms in genes related to vitamin D metabolism or transports, or even genes apparently not related to vitamin D, that predispose to lower serum 25OHD concentrations. A combination of such polymorphisms can thus identify subjects who are genetically predisposed to lower 25OHD concentrations than the general population. Identification of such variants requires very large-scale population studies, and genetic variants can only be used in further analysis if they are highly significantly associated at a genome-wide level ($P < 5 \times 10^{-8}$) with 25OHD. MR then uses this information as an epidemiologic method to test whether genetically lower 25OHD concentrations are associated with increased risk of a specific disease. MR has several advantages in comparison with observational studies or even RCTs. First, MR detects genetic variants that are randomly assigned at conception, which avoids the introduction of confounding factors. This is highly relevant because serum 25OHD concentrations are prone to confounding factors such as differences in climate, lifestyle, or body mass index (BMI). Second, given that alleles are inherited at conception, preceding disease onset, MR avoids the detection of reverse causation (whereby the later disease causes low 25OHD concentrations). Finally, MR evaluates lifelong effects of lower 25OHD, thus extending the observation period well beyond what an observational study or RCT can achieve. The limitations of MR are also obvious because it assumes a linear effect between low 25OHD and health outcome (and thus cannot evaluate a threshold effect). It also assumes that polymorphisms mediate their effects through serum 25OHD levels and have no other direct effect on the outcome studied. Finally, most MR studies published to date have only predict been able to predict up to 5% of the variation in serum 25OHD levels; but this may improve soon.

Skin. Based on studies of *Cyp27b1*-deficient mice, repair of the barrier function of the skin is impaired in the absence of vitamin D action. The major skin phenotype of both *Vdr*-null mice and children with *VDR* mutations, however, is the development of total alopecia. Hair development at birth is normal, but hair loss starts after the first catagen and ultimately leads to alopecia totalis associated with large dermal cysts. This alopecia is caused by the VDR itself because it is not observed in vitamin D–deficient wild-type mice or in mice with *Cyp27b1* mutations. No clear skin disease is linked to simple vitamin D deficiency in humans.

The very same photons that can photoconvert 7-dehydrocholesterol into previtamin D are also able to cause DNA damage and, ultimately, photoaging, increasing the risk for skin cancer, so exposure to the UVB or sunlight needed to produce vitamin D always involves a small but cumulative risk of skin damage. This risk is especially relevant for individuals with a fair skin type (phototypes 1 and 2). There is thus a very diffcult trade-off between ensuring safe exposure to sunlight so as to produce suffcient vitamin while avoiding long-term risks of skin damage and skin cancer. *Vdr*-null mice are more prone to develop skin cancer when exposed to UVB light. Although 1,25(OH)$_2$D and some of its analogs are able to generate a strong photoprotective effect against UVB-mediated events in cultured keratinocytes,[32] the overall prooncogenic effect of UVB is dominant.

Cell Proliferation and Cancer. Exposure to 1,25(OH)$_2$D of virtually all normal cells and even most malignant cells results in accumulation in the G0/G1 phase of the cell cycle. A general downstream effect is the regulation of the E2F family of transcription factors, which act as master switch for a very large number of genes involved in cell cycle progression. These E2F factors are under the control of the retinoblastoma proteins, and their phosphorylation state is regulated by cyclins and cyclin-dependent kinases (p18, p19, p21, or p27), many of which are regulated by 1,25(OH)$_2$D. However, 1,25(OH)$_2$D may also inhibit cell growth by interfering with signaling pathways initiated by transforming growth factor–β, epidermal growth factor, prostaglandins, Wnt ligands, and *c-myc*).[2,33] When exposed to chemocarcinogens, oncogens, or UVB light, *Vdr*-null mice develop more cancers (mammary cancer–type lesions, skin tumors, and lymphomas).[5] In addition, *Cyp27b1*-deficient mice kept alive for more than one year develop diverse types of spontaneous tumors. This was associated with increased oxidative stress, cellular senescence, and senescence-associated secretory phenotype molecules. Furthermore, 1,25(OH)$_2$D$_3$ prevented spontaneous tumor development.[34]

In humans, absolute *VDR* or *CYP27B1* deficiencies are rare, but vitamin D deficiency is very frequent. This obviously raises the question of whether vitamin D deficiency is associated with increased risk of cancer in humans. In most cross-sectional or observational studies, a higher cancer risk was found in subjects with serum 25OHD levels below 20 ng/mL. However, a few studies have also linked better vitamin D nutritional status with a higher prevalence of cancer or more aggressive types of cancer.[35] The final question is, of course, whether serum 25OHD is a predictor or has a causative relation with the overall cancer risk. A few RCTs (three out of 10) suggested some beneficial effects on cancer incidence (reviewed in Bouillon & Bikle[2]). Two recent large RCTs (the New Zealand ViDA[36] and the US VITAL[37] trials) independently evaluated the effects of vitamin D supplementation on cancer incidence and cancer mortality. The VITAL study[37] recruited more than 25,000 adults from 44 centers in the United States. The trial had a two-by-two factorial design to evaluate the potential benefits of vitamin D$_3$ (2000 IU/d) or omega-3 marine fatty acids (1 g/d). Adult males (>50 years) or females (>55 years) were followed for a mean duration of 5.3 years. The primary endpoints were invasive cancer (any type) and major cardiovascular events (a composite of myocardial infarction, stroke, or death from cardiovascular events). Many secondary events were also examined. The mean baseline vitamin D status (serum 25OHD concentration of 30.8 ± 10 ng/mL) was higher than that of the average American adult (based on comparison with the latest NHANES data). Subjects taking vitamin D supplements at baseline had, as expected, higher baseline 25OHD (33 ng/mL) than the others (27 ng/mL). The ViDA study[36] evaluated the effects of monthly high-dose vitamin D supplementation on more than 5000 New Zealand adults followed for a mean duration of 3.3 years. Subjects were randomized to receive either placebo or a dose of 200,000 IU of vitamin D at the start of the study, followed by a monthly dose of 100,000 IU (~3300 IU/d). Most of the participants had a normal vitamin D status at baseline (mean serum 25OHD of 26 ng/mL). Neither study found an effect of vitamin D supplementation on cancer incidence at 3.3 or 5.3 years' follow-up. Combining all vitamin D and cancer studies involving a total of more than 70,000 subjects, therefore, suggests that vitamin D supplementation of mostly vitamin D-replete adults (mostly White people) for approximately 5 years does not change their cancer risk. However, five independent trials suggest, in *post hoc* analysis, potential benefits on cancer mortality if all data are combined or when the follow-up is longer than 4 years.[38] In view of the long latency period for carcinogenesis, the link between a good vitamin D status and cancer incidence or mortality probably requires a very long follow-up time, well beyond what most studies so far have been able to do. MR studies are more appropriate to answer the effect of lifelong vitamin D status on cancer incidence. A large number of such MR studies have looked at this potential link. Overall, the existing MR studies support the protective effect of vitamin D on ovarian cancer,[39] but not on other types of cancer such as breast, prostate, and colorectal cancer, among others.[2]

In conclusion, preclinical data suggest that severe vitamin D deficiency may predispose to carcinogenesis, whereas exposure to high 1,25(OH)$_2$D levels may reduce cell proliferation and induce cell differentiation. Numerous observational studies link poor vitamin D status to increased risk of cancer or poorer prognosis for existing cancers. Many MR studies did not demonstrate an effect of genetically lower serum 25OHD concentrations on the risk of major cancers, although the power of most of these MR studies to predict changes in serum 25OHD was usually below 5% of the variation of serum 25OHD. RCTs dealing with a total population of more than 70,000 mostly White adults, however, did not find a reduced risk of cancer associated with vitamin D supplementation. However, several independent trials suggest, in *post hoc* analysis, potential benefits on cancer mortality. This effect is significant if all data are combined or when the follow-up is longer than 4 years. In view of the long latency period for carcinogenesis, the link between a good vitamin D status and cancer incidence or mortality probably requires a very long follow-up time that is well beyond what most studies so far have been able to do.

There are thus confusing data regarding a possible link between vitamin D status and cancer, and several options are still open:

- Option 1. The vitamin D endocrine system is redundant; the cell cycle is under such complex control that the vitamin D status is largely redundant for the genesis or evolution of human cancers.
- Option 2. Only total or near-total absence of vitamin D action has an influence on cell proliferation and cancer, as shown in animal models of *Vdr* or *Cyp27b1* deficiency. Such very severe vitamin D deficiency is so infrequent in the human population that the benefits of correction of such severe deficiency cannot be picked up in RCTs.
- Option 3. Carcinogenesis is such a slow process that the duration of the RCTs (up to 5–7 years) is insufficient to reveal the true role of the vitamin D endocrine system. Long-term and or severe vitamin D deficiency may play a (minor) role in the pathogenesis or evolution of (some) human cancers. The available data are insufficient to provide a clear answer.

Immune Function and Vitamin D. All immune cells express a functional VDR at certain stages of their differentiation. Antigen-presenting cells (dendritic cells and equivalent resident cells, as well as monocytes/macrophages) can synthesize 1,25(OH)$_2$D using the same enzyme as the kidney but controlled by immune stimuli instead of calciotropic hormones.[40] Finally, 1,25(OH)$_2$D regulates a wide range of genes that play crucial roles in the immune system. Vitamin D metabolites stimulate the innate immune system (largely mediated by monocytes/macrophages) by enhanced expression of a number of critical genes such as those encoding the pattern recognition receptor nucleotide oligomerization domain protein, the Toll-like receptor cofactor CD14, the antimicrobial peptides cathelicidin, defensin beta 2, defensin beta 104B, as well as multiple cytokines and chemokines.[2,40,41] A recent analysis[42] evaluated 10,933 participants of 25 RCTs and found a significant overall reduction in acute respiratory infections (odds ratio [OR] 0.88, 95%CI: 0.81–0.96) with the greatest benefits in subjects with severe vitamin D deficiency (<10 ng/mL) at baseline (OR 0.58, 95% CI: 0.40–0.82), with a number needed to treat for benefit of eight subjects. Subgroup analysis revealed that intermittent (monthly or less frequent) doses of vitamin D did not generate protection, whereas daily or weekly vitamin D supplementation was more effective (OR 0.81, 95% CI: 0.072-0.91). In the ViDA trial, however, no effects of vitamin D supplementation were found in acute respiratory infections in older adults.[43] This is not a total surprise, as the lack of effects may be attributed to the intermittent dosing and/or adequate vitamin D status at baseline, and thereby not contradict the Martineau 2019 metaanalysis. Tuberculosis is frequently associated with poor vitamin D status, and vitamin D is also able to accelerate the killing of intracellular mycobacteria.[44,45] Some, but not all intervention studies suggested a more rapid clearance of tuberculosis with correction of vitamin D deficiency.[46] In a large study of severely vitamin D-deficient children, however, vitamin D supplementation did not reduce the risk of developing active tuberculosis.[47] A total of 8851 children underwent randomization, and all had a baseline serum 25OHD level of less than 20 ng/mL. The mean 25OHD level at the end of the trial was 31 ng/mL in the vitamin D group and 11 ng/mL in the placebo group. The two groups received a weekly oral dose of either 14,000 IU of vitamin D_3 or placebo for 3 years. Tuberculosis was diagnosed in 21 children in the vitamin D group and in 25 children in the placebo group (adjusted RR 0.87; 95% CI: 0.49–1.55). A total of 29 children in the vitamin D group and 34 children in the placebo group were hospitalized for treatment of acute respiratory infection (adjusted RR 0.86; 95% CI: 0.52–1.40). The incidence of adverse events did not differ significantly between the two groups. Vitamin D supplementation therefore did not result in a lower risk of tuberculosis infection, tuberculosis disease, or acute respiratory infection compared with placebo among vitamin D-deficient schoolchildren in Mongolia. Whether this was related to prior tuberculin vaccination is unknown.[47a]

The acquired immune system reacts in opposite way than does the native immune system. Indeed, $1{,}25(OH)_2D$ inhibits dendritic cell maturation and generates coordinated action on T cell gene expression of key cytokines (IL-1, IL-2, IL-12, IL-17, INF-γ) and genes needed for antigen presentation to T cells (MHC class II and cosignaling proteins). Secondly, in collaboration with dendritic cells, $1{,}25(OH)_2D$ decreases the activity of Th1 and Th17 cells, while upregulating regulatory T cells.[2,48] This should have beneficial effects on the occurrence or evolution of autoimmune diseases. Vitamin D-deficient mice more easily develop a more severe type of such autoimmune diseases. For example, genetically predisposed NOD mice exposed to transient vitamin D deficiency early in life have a much higher incidence of T1DM than vitamin D-replete mice,[49] and *Cyp27b1*-deficient mice are more prone to several types of inflammatory bowel disease. Moreover, $1{,}25(OH)_2D$ and more potent and selective analogs can significantly reduce spontaneous or experimental autoimmune diseases in rodents, such as T1DM in NOD mice and experimental allergic encephalitis, nephritis, or inflammatory bowel disease in rodents. Studies of human autoimmune diseases are, however, more complicated. Polymorphisms of the *CYP27B1* gene and other genes involved in the vitamin D endocrine system are associated with a risk of T1DM in cross-sectional, as well as in family, studies. Consistent with data from NOD mice, several epidemiologic studies in humans report that vitamin D supplementation early in life may reduce later risk of T1DM. Risk reduction varied between 26% with cod liver oil to 78% with 2000 IU/d, with an overall effect of 30% reduction in five published reports.

A low vitamin D status has also been repeatedly associated with a higher risk for multiple sclerosis. A large prospective, nested, case-control study among more than 7 million US military personnel revealed that low 25OHD level was a strong risk factor for later occurrence of multiple sclerosis (OR of ~2 for serum 25(OH)D <20 ng/mL, with possibly even greater "protection" by higher levels).[50] However, as for T1DM, no controlled, randomized intervention studies have proved yet a causal relation between vitamin D (deficiency or insufficiency) and later occurrence of autoimmune diseases, but randomized trials (especially in genetically at-risk groups) should receive high priority. MR studies, despite their inherent limitations, are the best proxy for RCTs, as they enable evaluation of the consequences of lifelong lower vitamin D status on specific outcomes. Four independent MR studies revealed that genetically predicted lower serum 25OHD concentrations are associated with a higher risk of juvenile or adult-onset multiple sclerosis (reviewed in Bouillon & Bikle[2] and Jacobs et al.[51]). All these observations, therefore, suggest that preventing vitamin D deficiency in the perinatal period, early childhood, or adolescence may have long-lasting effects on autoimmune diseases. Moreover, there are several observations in mouse models that could explain such effects, such as the increased apoptosis of (potentially autoreactive) thymocytes or lymphocytes and the generation of regulatory T cells and natural killer T cells after exposure to $1{,}25(OH)_2D$. Several studies have looked at the effects of high-dose vitamin D supplementation (up to 40,000 IU/d) as add-on therapy with the aim of slowing the progression of multiple sclerosis, but no clear beneficial effects on progression of disability or relapse–free rate have been observed so far.[52,53] Similarly, as for multiple sclerosis, there are many suggestions that inflammatory bowel disease is linked with vitamin D deficiency, but a high-dose supplementation study did not reveal any benefit regarding the cumulative postoperative recurrence of Crohn disease.[54]

Cardiovascular System. *Vd*- null mice, as well as *Cyp27b1*-null mice, develop high-renin hypertension and cardiac hypertrophy that can be prevented by treatment with an angiotensin blocker. $1{,}25(OH)_2D$ decreases renin production, probably by direct regulation of gene expression via a VDRE in its promoter. Many other genes such as plasminogen activator inhibitor and thrombomodulin are also under the control of $1{,}25(OH)_2D$. Several *in vitro* studies have also confirmed beneficial effects on vascular smooth muscle cells and endothelial cells and thereby suggest that vitamin D may have overall beneficial cardiovascular effects (reviewed in Bouillon[55]). However, exposure to excess $1{,}25(OH)_2D$ may result in transdifferentiation of vascular smooth muscle cells into osteoblast-like cells and cause calcification of the vascular wall. Observational studies are consistent with these preclinical data. In normotensive and hypertensive individuals, there is an inverse association between 25OHD concentration and cardiovascular risk factors (such as hypertension) and cardiovascular events (ischemic heart disease, cardiomyopathy, stroke, and cardiovascular mortality).[56,57] Indeed, a metaanalysis of nearly 850,000 individuals concluded that subjects with the lowest serum 25OHD concentrations were at increased risk (RR 1.43) of cardiovascular events.[56] Based on such observational data, a 10 ng/mL higher serum 25OHD was associated with a RR of 0.90 (95% CI: 0.86–0.94), but the RR was not linear, as the lowest risk of major cardiovascular diseases (including heart failure) was found in subjects with serum 25OHD between 20 and 25 ng/mL.[57] Many risk factors of cardiovascular diseases such as hypertension, obesity, diabetes, lipid profile, smoking, physical activity, and other lifestyle aspects are also linked to vitamin D status, either causally or by reverse causality (e.g., lower physical activity and sun exposure resulting in poorer vitamin D status). Therefore, observational links are only hypothesis-generating and need confirmation by controlled supplementation studies. The results of randomized trials have been inconsistent, but a 2015 metaanalysis of 46 trials including 4541 participants found no significant effects of vitamin D supplementation on systolic or diastolic blood pressure.[58] The New Zealand ViDA RCT did not find a beneficial effect on peripheral blood pressure with a monthly dose of 100,000 IU of vitamin D compared with placebo. In a more in-depth subanalysis, a significant decrease in central blood pressure was found in a small group of subjects with baseline vitamin D deficiency.[59] In humans, a low vitamin D status is associated with a number of cardiovascular risk factors, including all aspects of the metabolic syndrome. A metaanalysis of 19 prospective studies (65,994 patients) revealed an inverse relationship between serum 25OHD levels (8–24 ng/mL [20–60 nmol/L]) and risk of cardiovascular disease (RR 1.03, 95% CI: 1.00–1.60, per 10-ng/mL [25 nmol/L] decrement in serum 25OHD).[60] Randomized trials, however, could not demonstrate a persistent effect of vitamin D supplementation on cardiovascular outcomes, including myocardial infarction and stroke, lipids, glucose, or blood pressure. Two recent megatrials (VITAL[37] and ViDA[61]) evaluated the effect of vitamin D supplementation on a set of cardiovascular events. Combining all RCTs involving more than 80,000 subjects and up to 5 years of follow-up, vitamin D supplementation of mainly vitamin D-replete subjects generated no cardiovascular benefits or harm.[55,62,63] Patients with chronic renal failure have a high frequency of cardiovascular problems, whereby most patients suffer from combined deficiency of 25OHD and 1,25$(OH)_2$D. Whether correction of their vitamin D status would improve their outcome is still debatable, but such patients may well be an excellent target group to study the role of the vitamin D endocrine system in a high-risk group of combined vitamin D deficiency and cardiovascular mortality.

Muscle, Muscle Function, and Falls. VDR is expressed in myoblasts and stellate cells but is probably absent in mature striated muscle cells. *Vdr*-null mice show maturation problems of their muscle fibers, with smaller muscle fibers and expression of embryonic markers even after weaning.[64] Genes that are typically expressed early in life (e.g., *myf-5*) are under negative control by 1,25$(OH)_2$D. Muscle-specific deletion of *Vdr* results in sarcopenia and impaired muscle function.[65] Patients with chronic renal failure and vitamin D deficiency (and thus combined deficiency of 25OHD and 1,25$(OH)_2$D) can develop severe myopathy and an inability to walk that can be promptly restored by appropriate vitamin D and/or analog treatment, similar to effects seen in patients with congenital *CYP27B1* deficiency. Observational studies show a relationship between low (<20 ng/mL, and especially <10 ng/mL) 25OHD levels and muscle weakness in children and elderly subjects.[66] Sarcopenia (progressive loss of muscle mass and strength) is highly prevalent in the elderly and is frequently associated with vitamin D deficiency. Many intervention trials have yielded inconsistent results on muscle function and body sway.[2] Based on results from 30 RCTs, Beaudart et al.[67] concluded that muscle strength modestly improved with vitamin D supplementation, especially if it was given to elderly subjects with severe vitamin D deficiency (<12 ng/mL) at baseline. Two Cochrane reviews extensively examined the effects of vitamin D supplementation on falls. One review concluded that vitamin D supplementation reduced the risk of falls in institutionalized patients (RR 0.63, 95% CI: 0.46–0.85). In ambulatory subjects a reduced risk of falls and fallers was only found in vitamin D-deficient and not in vitamin D-replete subjects. A recent *post hoc* analysis of the large New Zealand ViDA study, however, did not find a beneficial effect on the risk of falls with monthly doses of 100,000 IU of vitamin D.[26] This conclusion does not totally contradict the previous results, as the ViDA participants were mainly vitamin D-replete adults. Similarly, the US VITAL trial reported no effects of daily supplementation with 2000 IU of vitamin D on fall risks.[24] High-dose vitamin D supplementation, however, may increase the risk of falling. This was first observed by Sanders et al.[68] in elderly subjects treated with a yearly dose of 500,000 IU of vitamin D. The vitamin D-treated group had significantly more falls and fractures during the first 3 months after each loading dose. In addition, high monthly doses of vitamin D (with or without 25OHD) also increased the risk of falls in the high-dose groups.[69] Other studies confirmed a fall risk owing to high-dose vitamin D.[70]

In conclusion, there is at present no consensus regarding the potential effects of vitamin supplementation on muscle function, balance, and risks of falls. Older studies performed in elderly, mostly vitamin D-deficient subjects, suggested a small reduction in risk of falls. Vitamin D supplementation of vitamin D-replete New Zealand or US adults did not convey benefits or risk. Finally, a few studies reported that high intermittent doses or even simply high serum 25OHD may enhance the risk of falls in elderly subjects. Therefore, it seems that correction of severe vitamin D deficiency with modest regular doses of vitamin D is desirable.

Diabetes and Obesity. Vitamin D deficiency in experimental animals (rodents and rabbits) impairs glucose tolerance, but this is not consistently confirmed in *Vdr*-null mice. Many observational cross-sectional or prospective studies suggest a close link between low vitamin D status and T2DM. As example, a metaanalysis of 21 prospective studies involving 76,220 participants and 4996 incident T2DM cases showed a RR of 0.62 (95% CI: 0.54–0.70) of T2DM in subjects with serum 25OHD concentrations above 25 ng/mL compared with subjects having serum 25OHD concentrations below 12 ng/mL.[71] Small-scale intervention studies provide inconsistent results, sometimes with small benefits for one aspect of insulin sensitivity or glucose homeostasis, sometimes with null results, as summarized in a systematic review.[72] The large US D2d study was designed to investigate this relationship and to evaluate the effects of a dose of vitamin D (4000 IU/d) for a mean duration of 2.5 years on the conversion of prediabetes to T2DM. The criteria used to define prediabetes (fasting plasma glucose between 100 and 125 mg/dL or a 2-hour post-oral glucose tolerance test plasma level between 140 and 199 mg/dL or a glycated hemoglobin level between 5.7% and 6.4%) and T2DM were in line with the American Diabetes Association guidelines. Most study participants were vitamin D-replete at baseline, as their mean baseline serum 25OHD concentration was approximately 28 ng/mL.[73] In the intention to treat analysis, the hazard ratio (HR) to develop T2DM in the vitamin D group was 0.88 (95% CI: 0.75–1.04; $P = 0.12$). The same conclusion was reached for subgroups of participants (according to race or ethnicity, BMI, glycemic baseline criteria, or gender). In a *post hoc* nonpreplanned analysis of a small ($n = 103$) subgroup of subjects with severe vitamin D deficiency at baseline (serum 25OHD <12 ng/mL), the HR to progress to T2DM was more than halved (HR 0.38, 95% CI: 0.18–0.80). In an exploratory per-protocol analysis censoring data from participants who did not follow the protocol exactly, the HR to progress to T2DM was 0.84 (95% CI: 0.71–1.00). In subjects with a baseline BMI below 30 (approximately one-third of all participants), the HR to progress to T2DM was just significant at 0.71 (95% CI: 0.53–0.95). These are all subgroup analyses that should not be considered confirmatory, as multiple statistical adjustments were required. Mice with a deletion of *Vdr* or *Cyp27b1* develop a lower fat mass owing to increased energy expenditure.[74] In contrast, most observational studies in humans link vitamin D insufficiency to nearly all aspects of the metabolic syndrome—including obesity, insulin resistance, fasting blood glucose or T2DM, hypertension, and hyperlipidemia. Intervention studies, however, had no effects on body weight evolution. Low serum 25OHD concentration in obese or diabetic subjects may well be attributed to the decreased expression of hepatic CYP2R1, as shown in mouse models (reviewed in Bouillon et al.[3]). Indeed, hepatic Cyp2r1 expression (at the mRNA and protein levels) and activity are markedly reduced in mice with diet-induced obesity or diabetes. If this also applies to human obesity/T2DM, it may well explain the discrepancy between strong observation data and the results from RCTs.

Reproduction. Serum 25OHD concentrations are frequently low in pregnant women. A Cochrane analysis revealed that vitamin D supplementation in pregnant women has some beneficial effects on maternal health (preeclampsia and gestational diabetes) and the health of their offspring (low birth weight).[75] An independent overview of 43 systemic reviews[76] dealing with 204 original studies concluded that observational data suggested a link between poor vitamin D status and maternal outcomes (preeclampsia or gestational diabetes) or fetal outcome (small for gestational age). However, this was not confirmed in an overview of intervention studies, except for a slightly increased risk of giving birth to a child who was small for gestational age. A detailed analysis focusing on preeclampsia concluded that vitamin D supplementation dose dependently decreased the risk of preeclampsia (OR 0.35, 95% CI: 0.25–0.5).[77] However, a large supplementation study in pregnant Bangladeshi women with severe vitamin D deficiency did not reveal beneficial effects.[78] Therefore, it is not yet possible to draw a definitive conclusion regarding vitamin D supplementation during pregnancy. In view of the high frequency of poor vitamin D status before or during pregnancy, further studies on the possible benefits of vitamin D supplementation during pregnancy or in the perinatal period should receive high priority.

Safety. Doses of vitamin D below the upper limit defined by the Institute of Medicine (IOM) or European Food Safety Agency (EFSA) seem to be safe. A small increase in the risk of kidney stones was observed in the Women's Health Initiative study, but not in the more recent large-scale studies. No changes in kidney function were reported. Very high single-bolus doses (>300,000 IU), however, have been associated with a transient increase in risk of falls or fractures and should be avoided.[79] Additional studies suggest that high continuous doses of vitamin D given to elderly subjects, increasing their 25OHD well above 45 ng/mL, may increase their risk of falls.[69] Individuals with *CYP24A1* mutations are of course very sensitive to toxicity, as mentioned earlier (in the section on Metabolism) and should avoid all exposure to vitamin D or even extensive sunlight because of the risk of hypercalcemia, kidney stones, or nephrocalcinosis. An extensive safety study (Calgary study) showed that daily doses between 4000 and 10,000 IU/d may occasionally result in hypercalciuria or hypercalcemia and even may modestly decrease BMD. No increase in vascular calcifications was seen in subjects receiving 4000 to 10,000 IU/d during the 3 years of follow-up in the Calgary study.[28] Higher doses of vitamin D (or vitamin D metabolites) may cause classical calcemic toxicity (Table 50.1), and such signs and symptoms are usually only seen when serum 25OHD is well above 100 ng/mL.[80]

Mortality. Because vitamin D status is associated with so many major diseases, it is worth exploring whether vitamin D deficiency is associated with increased mortality. NHANES studies, along with similar studies in Europe, demonstrate that low serum 25OHD concentrations (especially <20 ng/mL) are associated with increased mortality, even when deaths during the first 3 years of follow-up were removed from the dataset to avoid detecting reverse causality.[81] The recent megatrials did not demonstrate an effect on mortality, but the subjects were younger and more vitamin D–replete at baseline than in previous studies summarized in a Cochrane analysis showing a modest decrease in mortality in association with vitamin D_3 supplementation (RR 0.94, *P* = .002).[82]

KEY POINTS

- A large set of preclinical data suggests that the vitamin D endocrine system may influence cell proliferation and cancer, as well as the immune and cardiovascular systems and many other tissues. Observation studies are largely in line with these data and suggest that poor vitamin D status is linked to major human diseases such as cancer, infections, and autoimmune, cardiovascular ,and metabolic diseases. Large randomized trials, however, have failed to confirm the beneficial effects of vitamin D supplementation, although most subjects were not severely vitamin-deficient at baseline. Mendelian randomization studies have produced largely "null" results, except for a consistent link between genetically low 25OHD status and multiple sclerosis.

CLINICAL USE OF VITAMIN D

To define the use of vitamin D or its metabolites or analogs, we need to define what should be measured to evaluate the vitamin D status, how to define the optimal vitamin D status, and finally who should receive vitamin D supplements.

Assays for Vitamin D and Metabolites: Methodology and Applications

Vitamin D and approximately 30 of its metabolites are found in plasma. The measurement of serum concentrations of vitamin D_2 or D_3 is of little clinical value because it only reflects recent exposure to UV light or nutritional intake. Serum 25OHD concentration rather than serum vitamin D_3 is an excellent reflection of the vitamin D status because of the rapid conversion of vitamin D into 25OHD and its long plasma half-life.[12] Its plasma concentration varies widely in normal subjects because of large variations in endogenous and exogenous vitamin D supplies. Plasma 25OHD thus behaves as a true vitamin, in that its concentration depends on nutritional supply or synthesis in the skin after exposure to UVB light. Low exposure to UV light and low vitamin D intake are quite common in infants and elderly subjects if food sources are not supplemented with vitamin D. Plasma 25OHD concentrations are indeed low at birth (usually approximately half the maternal concentration because of the 2:1 ratio of maternal to fetal DBP concentration), and the natural vitamin D content of milk is low. During the evolution of vertebrates and humans, sun exposure was therefore the natural solution to prevent rickets. Members of African tribes that retain their traditional lifestyles have a mean serum 25OHD of approximately 45 ng/mL.

The metabolism of 25OHD into $1,25(OH)_2D$ and $24,25(OH)_2D$ is tightly controlled by hormones, ions, and humoral factors. The plasma concentration of $1,25(OH)_2D$ is therefore regulated as a true hormone, and measurements of its concentration can be useful for clinical exploration of unusual cases of rickets, osteopenia, and hypo- or hypercalcemia. The serum concentration of $24,25(OH)_2D$ usually reflects the concentration of 25OHD, and an abnormal $24,25(OH)_2D$:25OHD ratio is the best parameter for biochemically defining *CYP24A1* mutations. Measurements of the serum concentration of several vitamin D metabolites are essential for clinical or research purposes. Most laboratories prefer routine immunoassays for measurement of 25OHD and $1,25(OH)_2D$. The quality control of such assays has substantially improved thanks to interlaboratory quality-control studies. The major problem with routine 25OHD assays is accuracy, as vitamin D deficiency is defined by absolute concentration. Tandem mass spectrometry after liquid chromatography is now the gold standard for measuring 25OHD and other vitamin D metabolites. Above all, accuracy should be continuously monitored using validated control samples.[83] Whether free 25OHD or free 1,25$(OH)_2D$ is superior to total concentrations for clinical purposes is still an open question.[84] In countries where vitamin D_2 is (frequently) used, $25OHD_2$ should be measured as well as $25OHD_3$. In the case of immunoassays, this implies that the antibodies used should not discriminate between the two metabolites. When measured by tandem mass spectroscopy, then the results are preferably expressed as serum $25OHD_3$ and $25OHD_2$, both separately and combined. Because 3-epi-25OHD can make up a large percentage of total 25OHD, especially in younger children, care should be taken to minimize or eliminate the interference of this low-activity metabolite. The serum concentration of 25OHD varies widely between and even within the same population. Table 50.2 summarizes a number of factors influencing serum 25OHD. Serum 25OHD concentrations are higher in subjects with a higher vitamin D intake (e.g., higher serum 25OHD in Scandinavian countries because of higher consumption of oily fish) or higher exposure (e.g., as in Masai tribes or Brazil) or lower exposure (e.g., in many countries in North Africa, Middle East, or the Gulf states, or in countries with high latitude where no effective vitamin D synthesis is possible for many months) to UVB sunlight. Mismatch between skin color and sunlight hours (owing to migration) also markedly influences serum 25OHD. Sunscreen use may decrease endogenous vitamin D synthesis, but most subjects do not use the required amount of sunscreen or stay exposed to sunlight for longer than the recommended time. Therefore, in real-life situations, the use of sunscreen has very limited influence on serum 25OHD concentrations. True excess levels of 25OHD are mainly as a result of intake of pharmaceutical amounts of vitamin D or because of rare mutations of *CYP24A1*. Too-low serum 25OHD concentrations can be the result of abnormal metabolism (Table 50.2) or to a number of diseases that cause decreased intestinal absorption or enhanced urinary loss of vitamin D (metabolites). Table 50.2 also lists risk groups for poor vitamin D status. The thresholds defining vitamin D deficiency or excess are described in the following section.

The serum concentration of 1,25$(OH)_2D$ (and especially its free concentration) is feedback-regulated and is therefore more within a narrower range in normal subjects compared with serum 25OHD. Decreased serum 1,25$(OH)_2D$ concentrations are mainly attributed to substrate deficiency (as in nutritional rickets), genetic or acquired CYP27B1 deficiency, hormonal diseases (such as too little PTH or excess FGF-23 activity), or decreased serum DBP concentrations (Table 50.3). Excess 1,25$(OH)_2D$ is rarely attributed to substrate excess and mostly the consequence of hormonal imbalances (PTH excess/FGF-23 deficiency), DBP excess, or rarely vitamin D resistance (VDR mutations) (Table 50.3).

TABLE 50.2 **Serum Concentrations of 25OHD**

Normal Fluctuation According to:

Dietary intake (+)[a]
Sun (ultraviolet [UV] light) exposure (+) influenced by seasonal lifestyle and cultural habits
Age (–)
Skin pigmentation (–)
Latitude (–)
Sunscreen use (–)

Increased 25OHD Concentration

Exposure to pharmaceutical vitamin D[b]
Excess exposure to nutritional vitamin D
Excess exposure to UV light
CYP24A1 deficiency

Decreased 25OHD Concentration

- Genetic or acquired deficiency of CYP2R1
- Genetic or acquired excess of CYP4A3
- Combined deficiency of access/exposure to nutritional vitamin D and UV light
  - Major risk groups include:
    - Infants, especially when born in late winter
    - Women and children of immigrants with pigmented skin living in temperate climates
    - Elderly individuals with limited mobility
    - Subset of the population with low exposure to sunlight because of socioeconomic, religious, or cultural reasons
- Decreased intestinal absorption of vitamin D associated with fat malabsorption (e.g., associated with biliary cirrhosis)
- Short bowel syndrome
- Exocrine pancreas insufficiency
- Gluten enteropathy
- Increased loss or catabolism of vitamin D
- Nephrotic syndrome
- Chronic liver P450 activation by drugs (e.g., barbiturates or antiepileptic drugs)
- Low calcium intake or absorption

[a] Positive or negative effects are indicated by + or –, respectively.

[b] Vitamin D toxicity with hypercalciuria, hypercalcemia, nephrocalcinosis, kidney stones, metastatic calcification, etc., is only observed if 25OHD concentrations exceed 100 ng/mL. Without access to pharmaceutical vitamin D, it is therefore uncommon to develop clinical vitamin D toxicity.

Optimal Serum 25OHD Concentration

Vitamin D is a threshold nutrient, and thus a too-low supply of the substrate creates a deficiency of the active hormone and thus of VDR activation. Over the last decades, and even last century, the optimal vitamin D status has been a point of intense discussion. Many governmental and scientific societies have brought together a very large number of experts to define the minimal threshold for vitamin D status based on serum 25OHD concentrations. All guidelines are unanimous in defining serum 25OHD concentrations below 10 or 12 ng/mL as severe deficiency with increased risk for clinical consequences such as rickets or bone problems in general at any age (Fig. 50.2). This threshold is also in line with the intestinal absorption of calcium as defined by studies using the best technology for the estimation of intestinal calcium absorption. Indeed, calcium absorption and serum 1,25$(OH)_2D$ are markedly decreased when serum 25OHD drops below 5 ng/mL, and no further increase is observed in otherwise healthy subjects once serum 25OHD exceeds 10 to 12 ng/mL.[35,85] Apart from the UK guidelines (Scientific Advisory Committee on Nutrition [SACN]),[86] most other guidelines recommend a serum 25OHD concentration of at least 20 ng/mL for optimal bone health so as to avoid compensatory homeostatic mechanisms (mainly increased serum PTH). Most of these guidelines extensively describe the arguments for this choice, with specific focus on the results of randomized trials rather than on observational data. In addition, IOM adds another dimension to the discussion by arguing that serum 25OHD concentrations of 16 ng/mL would be sufficient for approximately half of the healthy North American population, and that 20 ng/mL would be sufficient

TABLE 50.3 **Serum Concentration of $1,25(OH)_2D$**

Decreased Concentrations	Increased Concentrations
Substrate Deficiency[a]	**Substrate Excess**[b]
(e.g., nutritional rickets, intestinal malabsorption)	
25OHD-1α-Hydroxylase Enzyme Deficiency	**25OHD-1α-Hydroxylase Enzyme Excess**
Inborn: Vitamin D–dependent rickets	Primary or tertiary hyperparathyroidism
Organic: Renal insufficiency or anephric patients	Hypothyroidism
Functional:	Glucocorticoid excess
Hypoparathyroidism	Acromegaly
Pseudohypoparathyroidism	Granulomatous diseases
Hypomagnesemia	Idiopathic hypercalciuria
Tumoral osteomalacia	Hypophosphatemic rickets type 2 (+hypercalciuria)
Hypercalcemia of malignancy	Pregnancy
Hyperthyroidism	Nutritional calcium deficiency
Morbus Addison (acute)	Williams syndrome
Severe insulin deficiency	
X-linked hypophosphatemia	
Rhabdomyolysis	
Tumoral calcinosis	
DBP Deficiency	**DBP Excess**
Fetus	Pregnancy
Nephrotic syndrome	Oral estrogen use
Liver cirrhosis	
Genetic mutation	
	End-Organ Resistance
	True vitamin D resistance (so-called vitamin D-dependent rickets type 2)

DBP, Vitamin D–binding protein.

[a] In many cases of rickets or osteomalacia, $1,25(OH)_2D$ concentrations are still measurable or even nearly normal. This may be as a result of recent (and insufficient) access to vitamin D after long-term vitamin D deficiency. Nevertheless, such concentrations are too low in comparison with the degree of secondary hyperparathyroidism. Regardless, 25(OH)D is a better marker for vitamin D deficiency than $1,25(OH)_2D$. A similar situation is observed in hypothyroidism, as the precursor hormone T_4 is a better marker for clinical hypothyroidism than the real hormone, T_3.

[b] Vitamin D excess only increases serum $1,25(OH)_2D$ when renal function remains normal and/or parathyroid hormone secretion is elevated. Frequently, $1,25(OH)_2D$ levels are low or normal in vitamin D toxicity.

for 97.5% of the population.[87] The Nordic (Scandinavian),[88] DACH (German-speaking countries),[89] and EFSA[90] guidelines also support this threshold of 20 ng/mL. Several scientific societies also supported 20 ng/mL as the definition of "normal vitamin D status or vitamin D sufficiency" (European Calcified Tissue Society, National Osteoporosis Society,[30,30a]). The Dutch Health council considered 12 ng/mL sufficient to prevent rickets and osteomalacia and could not find strong, hard data to recommend 20 ng/mL for adults, except for the elderly, and therefore recommended a mixture of SACN and IOM targets for all children and adults (SACN target), except for the elderly (IOM target). The Endocrine Society (US) and a few other scientific societies, however, recommend serum 25OHD concentrations above 30 ng/mL as being the minimal concentration to define vitamin D sufficiency. Thus, they define levels between 20 and 30 ng/mL as insufficient for optimal health in general.[91] A few regional scientific organizations, such as the Central European countries and the Italian Endocrinologists, support this interpretation. Some grass-root organizations recommend still higher 25OHD concentrations such as those found in subjects with extensive daily sun exposure (such as the Masai tribe in Africa), which are presumably similar to those of early humans.[92] There is no general agreement about the safe upper level of 25OHD. Values above 100 ng/mL (and especially >250 ng/mL) have been associated with hypercalcemia and its health implications (Table 50.1), and are thus to be avoided. Values above 50 ng/mL have been occasionally associated with increased risk of falls, fractures, or bone loss, and most guidelines therefore do not recommend values above this threshold (Fig. 50.2). In NHANES or European surveys, very few subjects not taking vitamin D supplements have spontaneous serum concentrations of 25OHD above 50 ng/mL and among the Masai tribe, who have extensive full-body exposure to sunlight, very few individuals have concentrations above 70 ng/mL. Nature has many inbuilt defense systems against vitamin D excess; nevertheless, in the absence of clear benefits of very high serum 25OHD concentrations (>50 ng/mL), it seems wise to avoid such levels.

Worldwide Vitamin D Status

There are an enormous amount of publications reporting the vitamin D status of individuals in different countries around the world. Unfortunately, most studies did not use assays validated for accuracy and did not use a sampling technique that enabled them to be representative of the country or region. Nevertheless, such data provide reasonably approximate data on vitamin D status around the world. NHANES data are an exception, as they are representative for the US population, and the assay results have recently been recalibrated according to the standards of The National Institute of Standards and Technology to provide accurate results.[81] In addition, NHANES has collected serum samples for many decades so that long-term changes can be calculated. The results reveal a fairly stable vitamin D status over many years (after correction for drift in assay results), despite an increasing use of vitamin D supplementation in the US population. Approximately 5% of the US population has a serum 25OHD concentration below 10 ng/mL, whereas approximately 18% has a level below 20 ng/mL. Although there are a very large number of reports on the vitamin D status of individuals in European countries, there has been no systematic survey using representative sampling and accurate methodology. On behalf of the European Calcified Tissue Society, Lips et al. provided a summary of approximately 100 studies conducted in different European or Middle-East countries.[30] The best situation, unexpectedly, is found in Northern Europe, where only between 1% and 8% of the population has a serum 25OHD concentration below 12 ng/mL, whereas this percentage is higher in most Western European countries (5%–31%). In Southern and Eastern Europe, there is such a wide variety of results that an easy summary is not possible, but overall the frequency of severe deficiency is high. In the Middle East, the Gulf states, and North African countries, between 30% and 90% of the population has severe vitamin D deficiency. When a conservative threshold of 20 ng/mL is used, then approximately 40% of the total European population can be considered "modestly" vitamin D-deficient. These data are, of course, compiled from studies that analyzed different populations and used different methodologies. Cashman et al., however, recalibrated the assay results from several European RCTs to provide a better comparison with NHANES data. According to this analysis, approximately 13% of subjects were severely vitamin D-deficient, and approximately 40% had a serum 25OHD concentration below 20 ng/mL.[93] One study recently generated data representative of the adult Portuguese population[94]: approximately 21% of the 4000 subjects had

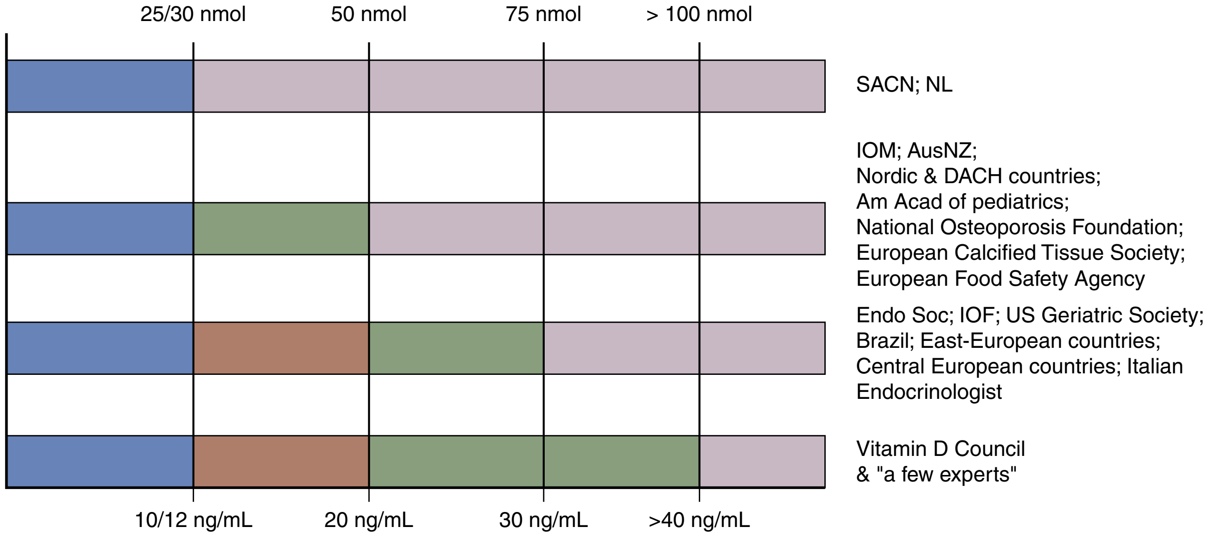

Fig. 50.2 Defining optimal vitamin D status as evaluated by serum 25OHD concentrations. Many guidelines (produced by governmental or scientific organizations) have tried to define thresholds for optimal vitamin D status in the normal population based on the most frequently used biomarker, serum 25OHD. All guidelines conclude that serum 25OHD concentrations should be above 10/12 ng/mL (25/30 nmol/L), and therefore levels below this threshold are indicated in red. Most experts now call this situation "severe vitamin D deficiency." The Institute of Medicine guidelines and many other guidelines consider a serum 25OHD level between 30 and 50 ng/mL as less than optimal. Indeed, these experts consider a serum 25OHD level of approximately 16 ng/mL to be sufficient for approximately 50% of the normal population and values above 20 ng/mL to be sufficient for approximately 97.5% of the population. Therefore, that range (12–20 ng/mL or 30–50 nmol/L) is indicated in orange. These guidelines consider serum 25OHD above 20 ng/mL as optimal, so we have indicated this range in green. The upper range of optimal 25OHD levels is disputed, but most guidelines consider 50 ng/mL to be the upper limit of normal values because of a combination of lack of proof of additional health benefits of concentrations higher than 50 ng/mL and some hints that such high values may have negative health consequences (especially with regards to falls and bone health). For details see the text. The Endocrine Society considers serum 25OHD between 20 and 30 ng/mL as "insufficient" and recommend all subjects (and especially subjects at risk of vitamin D deficiency) to aim for concentrations above 30 ng/mL. Therefore, we have indicated this range in yellow. A few organizations consider that serum 25OHD levels should be as high as they are in tribes with lifestyles that resemble those of early humans, and therefore suggest than we should all have serum 25OHD levels well above 40 or 50 ng/mL. Classical calcium-related toxicity is rarely found when serum 25OHD levels are lower than 100 ng/mL. We have therefore indicated higher 25OHD concentrations in red to denote their potential toxicity. *SACN,* Scientific Advisory Committee on Nutrition; *NL,* the Netherlands; *IOM,* Institute of Medicine; *NZ,* New Zealand; *IOF.* International Osteoporosis Foundation. serum 25OHD concentrations below 10 ng/mL (the highest risk factors included living in the Azores, winter and spring season, obesity, and old age), whereas 67% had serum 25OHD concentrations below 20 ng/mL, with an overall concentration of 17 plus or minus 7 ng/mL (mean ± standard deviation). Asia is of course a large continent that comprises very different climates and lifestyles. Vitamin D deficiency is, however, frequent in some regions such as Mongolia (with one of the lowest mean 25OHD concentrations in children and a high prevalence of rickets), Northern China, or Northern India, and, of course, as mentioned earlier, in the Middle East and the Gulf states.

Africa, the cradle of mankind and relatively close the equator, was for a long time considered to be relatively free from vitamin D deficiency. However, a recent overview of available publications (with an unfortunate lack of standardization) revealed that approximately 18% of the population has severe vitamin D deficiency (especially in North and South Africa), whereas approximately one-third of the African population has levels below 20 ng/mL.[95] The Middle East and the Gulf states have the poorest vitamin D status, and severe vitamin D deficiency is also observed in some areas of Northern India and China.

KEY POINTS

- Serum 25OHD is the best marker of vitamin D status. Most international guidelines recommend serum 25OHD levels between 50 and 125 nmol/L (20L50 ng/ml). Severe vitamin D deficiency (serum 25OHD <30 nmol/L or 12 ng/mL) is, however, still frequent around the world, affecting more than 5% of the US population and 14% of the European population and an even higher percentage of people living in the Middle East, North Africa, Northern India, and China. Special risk groups include individuals with poor exposure to sunlight and individuals with dark skin living in temperate climate zones. A daily intake of 40–1000 IU of vitamin D can avoid such deficiency in most subjects.

Vitamin D Requirements

Most subjects synthesize sufficient vitamin D by regular exposure to sunlight combined with a (usually modest) dietary intake of vitamin D. Additional vitamin D supplementation is of course not necessary in this situation. Because UVB light is photodamaging to skin DNA,

(For details see text and Edouard T, Alos N, Chabot G, et al. Short- and long-term outcome of patients with pseudo-vitamin D deficiency rickets treated with calcitriol. *J Clin Endocrinol Metab.* 2011;96:82–89.)

with a host of associated long-term consequences, there is a difficult trade-off between avoiding excess exposure and spending just enough time in the sun to produce the necessary amount of vitamin D. It is not possible to formulate universal advice on reaching this optimal balance because it depends on many factors such as skin pigmentation, intensity of UVB light (which depends on geography, season, and climate), and extent of exposed skin. There are, however, a few general rules such as avoidance of sun burning or prolonged exposure. Indeed, UVB damage increases with increased duration of exposure, whereas vitamin D production rapidly reaches a plateau as the newly synthesized vitamin D is degraded by prolonged UVB exposure. Young children's skin is also more sensitive to UVB damage, and therefore it is generally advised to avoid direct exposure to sunlight for infants and small children.

The vitamin D requirements needed to meet these minimal serum 25OHD concentrations have been extensively evaluated in many guidelines.[96] For infants and small children there is wide unanimity that a daily supplement of 400 IU is sufficient to prevent rickets and increase serum 25OHD well above 12 ng/mL. According to the UK SACN experts, this dose should be sufficient at any age. Most other guidelines, however, recommend that older children, adults, and pregnant women who have minimal exposure to sunlight (or endogenous vitamin D production) take 600 IU daily. For elderly subjects a slightly higher dose of 800 IU/d is recommended by most guidelines. These conclusions, as summarized in the IOM report and subsequently in other guidelines, were based on mean serum 25OHD concentrations achieved by administering different doses of vitamin D in intervention studies. A reanalysis of the data using individual data rather than mean study results, however, suggests that higher daily doses may be needed, and are moreover age-dependent, whereby 1200 to 1600 IU/d may be needed to reach optimal values in 97.5% of subjects.[97] To achieve serum 25OHD concentrations above 30 ng/mL, higher doses with great interindividual variations may be needed. These recommendations are intended for the general population. Table 50.4 summarizes several recommendations for age-related daily vitamin D requirements for subjects with minimal exposure to sunlight. These guidelines of course specifically mention that, in some disease states different doses of vitamin D may be needed. Patients with intestinal malabsorption (including many subjects with bariatric surgery), patients with increased catabolism (such as patients taking antiepileptic drugs), or patients with renal loss of DBP/25OHD or chronic renal failure in general usually have higher daily replacement needs and require individual follow-up. Obese subjects frequently have a low vitamin D status, and thus a higher than usual intake can be recommended.

Choice of Vitamin D Supplementation. Vitamin D (either D_3 or D_2) for infants and children is usually given as a daily supplement or added to bottle milk. Vitamin D_3 and D_2 are nearly equipotent when given on a daily basis, but vitamin D_2 is somewhat less potent than D_3 when given intermittently in weekly or monthly doses. Vitamin D_3 given in weekly or monthly doses (calculated to be equivalent to daily doses), but is nearly equipotent to daily supplements. The absorption of vitamin D is slightly but inconsistently modified by simultaneous intake of food or fats. Much higher doses given once or a few times a year have been associated with transient increased risk for falls and fractures and are thus no longer recommended.

Calcifediol or 25OHD is used in a few countries as alternative for vitamin D. The potency of 25OHD is approximately 3-fold higher than that of vitamin D itself when given to otherwise healthy postmenopausal women.[98] Calcifediol more rapidly restores serum 25OHD concentrations because of its better intestinal absorption (nearly 100%) and because it bypasses the need for hepatic CYP2R1-mediated 25-hydroxylation of vitamin D. The higher solubility of 25OHD also assures very high intestinal absorption even in case of intestinal fat malabsorption, and thus may be the preferred option in such cases. The increase in serum 25OHD concentration after vitamin D intake does not increase linearly, as the "delta 25OHD" is higher when the baseline vitamin D status is low and decreases with increasing doses of vitamin D, reaching a plateau 25OHD value with high vitamin D intake. The increase in serum 25OHD is more linearly related to the dose of calcifediol.

The use of $1,25(OH)_2D$ or 1a-OHD is restricted to situations of (genetic or acquired) loss of CYP27B1 activity, such as in patients with CYP27B1 mutations, patient with advanced renal failure (to prevent severe secondary hyperparathyroidism), or patients with hypoparathyroidism.

Thousands of vitamin D analogs have been synthesized and evaluated for their ability to treat, among other conditions, osteoporosis, cancer, and immune disorders. Only a very few analogs have made it into clinical practice. Calcipotriol is the first-line topical treatment for psoriasis. A few analogs (especially paricalcitol) are used in patients with advanced chronic renal failure because of a modestly greater effect on serum PTH than on serum calcium. Eldecalcitol is used in Japan for the treatment of osteoporosis but is not available in most countries.

SUMMARY

Vitamin D has been used for almost a century to prevent or cure nutritional rickets. Although the success rate of supplementation in infants and children is excellent, implementation is still problematic in many areas of the world. A dedicated WHO-sponsored action program similar to that instituted to prevent iodine deficiency disorders is long overdue and should preferably be part of a more general childcare health project dealing with nutrition and vaccination programs.

Vitamin D is a precursor for a secosteroid hormone, 1,25(OH)$_2$D, which acts as a ligand for a specific receptor, VDR, and regulates a very large number of genes. It is a key regulator of calcium and phosphate homeostasis through regulation of calcium transporters in the intestine and other calciotropic hormones (PTH and FGF-23). Many other clusters of genes involved in a wide variety of actions such as cell proliferation or immunity are also under the control of 1,25(OH)$_2$D, making extraskeletal activity plausible.

Severe vitamin D deficiency, as defined by serum 25OHD concentrations below 10 ng/mL, is present in approximately 7% of the world population and is much more prevalent in North Africa, the Middle East, and parts of Asia, affecting both young and older individuals. There is probably not a simple strategy that would solve this issue in all these countries. Individualized regular intake of supplements may solve the problem, but vitamin D supplementation of frequently consumed food items may well be the best strategy.

Pregnancy does not increase the need for vitamin D; nevertheless, many young women have a poor vitamin D status. Because it is plausible that this deficiency has negative consequences for the health of both the mother and her offspring, a dedicated action program as part of prenatal care should be developed and implemented.

The elderly frequently have increased fracture risk, poor vitamin D status, and lower-than-optimal calcium intake. Vitamin D supplementation has not proven to reduce fracture risk, and isolated calcium supplementation was also not effective. However, combined calcium and vitamin D supplementation has been repeatedly shown in several metaanalyses to be able to reduce hip and major fractures by 10% to 20%. All guidelines and most science organizations therefore recommend a daily supplement of approximately 800 IU of vitamin D together with optimal calcium intake through diet and or calcium supplements.

Approximately one-third of the world population has a 25OHD serum concentrations between 10 and 20 ng/mL, which is considered to be suboptimal because this state stimulates compensatory mechanisms to maintain normal calcium and phosphate homeostasis. This situation may affect the general population but is more frequent in specific risks groups such as people with limited exposures to sunlight because of climatic reasons, those with religious or cultural practices that involve covering the body, individuals with dark skin living in moderate climates, or anyone who does not produce sufficient endogenous vitamin D owing to lack of exposure to sunlight.

Most current guidelines are based on a large set of studies dealing with bone health and did not consider the evidence of potential extraskeletal benefits of vitamin D supplementation of sufficient quality to adjust their conclusions. Over the last years the results of many RCTs, and especially of several major megatrials or metaanalyses, have been published and provide data on potential extraskeletal effects of vitamin D supplementation. These data clearly show that vitamin D supplements given to mostly vitamin D-replete subjects do not convey health benefits for the skeleton or for general health. Therefore, the widespread belief among many scientists and lay people that improving vitamin D status by taking regular supplements may decrease the risk of many major diseases and improve general health is not supported by large-scale clinical trials or by MR studies. Table 50.5 summarizes the potential extraskeletal health benefits of vitamin D supplementation, although most of the effects described were mainly observed in subjects with poor vitamin D status at baseline.

Whereas over the last two decades the most attention was paid to the potential benefits of higher than usual vitamin D supplements for mitigating many major extraskeletal disorders, it is time to reorient basic and clinical research in the vitamin D field.

First, severe vitamin D deficiency (defined as serum 25OHD <12 ng/mLs) is still widely present around the world. It can be rather easily eliminated by appropriate implementation policies using small daily doses of vitamin D (~400 IU). This would allow the eradication of nutritional rickets and other consequences of severe vitamin D deficiency.

Second, vitamin D deficiency (defined as serum 25OHD <20 ng/mL) affects more than one-third of the world population. Combined use of calcium and vitamin D by elderly subjects probably reduces their risk of bone loss and fractures, especially because many of them have poor calcium and vitamin D statuses. Other risk groups for (severe) vitamin D deficiency are well known, and specific approaches are needed to define the benefits of supplementation, as well as the best long-term strategies, to eliminate such deficiency.

Third, many pregnant women have a rather poor vitamin D status. Correction of such deficiency may have health benefits for mothers and their offspring, but better data are needed to define who should receive how much vitamin D and when.

Fourth, the extraskeletal health benefits of vitamin D are probably much lower than many experts and lay people have believed over the last decades. Nevertheless, there is enough evidence of such benefits (summarized in Table 50.5) to guide future research. All these extraskeletal effects should be interpreted with caution, as the observations were frequently based on *post hoc* or subgroup analysis and therefore will require validation in additional dedicated trials.

TABLE 50.5 **Potential Extraskeletal Benefits of Vitamin D Supplementation Based on Analysis of Secondary Endpoints or *Post Hoc* Analysis of Recent Major Supplementation Trial or Mendelian Randomization Studies**

1. Reduce the risk of upper respiratory infections
2. May improve lung function, especially in subjects with asthma, chronic obstructive pulmonary disease, or chronic smokers
3. May improve proximal muscle strength
4. May decrease the risk of falls of elderly subjects
5. May decrease the progression of prediabetes into type 2 diabetes
6. May improve maternal health (especially preeclampsia and gestational diabetes)
7. May decrease cancer mortality (without changing the incidence of cancer)
8. May modestly reduce mortality risk of elderly subjects
9. May decrease the risk of multiple sclerosis (as based on several Mendelian randomization studies)

The most important message generated by the recent megatrials is that vitamin D supplementation of mostly vitamin D-replete adults does not provide major health benefits. Vitamin D supplementation should thus be focused much more selectively on the millions of subjects with modest or severe vitamin D deficiency. The major risk factors for such poor vitamin D status are well-defined, and healthcare policy should address these risk groups with adequate strategies. There are still a large number of ongoing clinical trials that may convey additional insight in the coming years. Moreover, using the power of MR we can now predict larger lifetime changes in vitamin D status. Such studies may generate data that can further modify or fine-tune the present conclusions.

Bone is a dynamic tissue that develops and maintains the skeleton to fulfill at least five primary functions in higher vertebrates: (1) the skeleton provides the crucial lever arms that allow muscular activity to generate movement; (2) the skeleton provides rigid protection for internal organs, including the brain and spinal cord; (3) the skeleton is the site for storage and controlled systemic release of calcium and other ions, which are essential for electrolyte homeostasis of the extracellular fluid; (4) bones house the bone marrow and participate in the genesis of hematopoietic cells by providing the essential stromal, vascular, and osteogenic niches that interact with hematopoietic precursors; and (5) the skeleton signals in ways that contribute to systemic glucose homeostasis and global energy metabolism.

A number of distinct cell types control the development of bone and regulate its functions. Skeletal development and growth are driven to a large extent by the differentiation of chondrocytes, which form and make up cartilage, and of osteoblasts, which build mineralized bone. These cells derive from mesenchyme-derived populations of skeletal stem and progenitor cells (SSPCs). Postnatally, the skeleton is continuously turning over in a process called bone remodeling. In this process, packets of bone are constantly being removed and replaced to meet the skeleton's mechanical demands by providing maximal strength from minimal material, while at the same time allowing the repair of microcracks and the accretion and release of calcium and phosphate. The principal cellular players in this process are the bone-forming osteoblasts and the osteoclasts, giant multinuclear cells derived from hematopoietic precursors that break down (resorb) bone. The quantitatively dominant cell type in adult bone and, in many ways, the master cell that coordinates the activity of the others is the osteocyte, which is derived from osteoblasts and buried within the bone matrix. The roles of osteocytes are not fully understood but include the sensing of mechanical forces, the regulation of bone formation and resorption, and the regulation of calcium and phosphate homeostasis. Bone development and maintenance are closely associated with and dependent on angiogenesis, putting vascular endothelial cells in the picture as a further crucial cell type in bone.

MECHANISMS OF SKELETAL DEVELOPMENT

During embryonic development, the skeleton is established by the coordinated formation of well over 200 separate bones at sites distributed all over the body. Two distinct mechanisms are responsible for the development of bones—intramembranous and endochondral ossification—both of which depend on the coordinate growth, differentiation, function, and interaction of various cell types. Intramembranous ossification is responsible primarily for the formation of most of the craniofacial elements and much of the scapulae and clavicles. In contrast, all the long bones of the limbs and the vertebrae and ribs of the trunk develop through endochondral ossification. This term connotes the formation of mineralized bone through the deposition of true bone matrix on top of scaffolding cartilaginous anlagen.

Intramembranous Ossification

The cranial and facial bones are derived largely from the neural crest through the process of intramembranous bone formation.[1] In areas where bones are formed, mesenchymal precursor cells aggregate and form regions of high cell density called condensations. In intramembranous bones, the cells in these condensations then differentiate directly into osteoblasts that deposit "osteoid" or bone matrix rich in type I collagen, a process that occurs in close spatial interaction with vascular tissue. As the osteoblasts mature, the bone matrix becomes progressively mineralized. Terminally differentiated osteoblasts eventually become entrapped in the bone as osteocytes. Membranous bones that derive from condensations that never form chondrocytes during development are restricted to the flat bones of the skull (calvarial bones and mandibles) and parts of the clavicles and scapulae. The subperiosteal bone collar or provisional cortex of long bones can be considered to form also by intramembranous bone formation, because the osteoblasts in this region differentiate directly from the perichondrial/periosteal mesenchyme and form bone adjacent to, instead of directly upon, a cartilage-derived matrix (see later). Of note, unlike the formation of intramembranous bone directly from condensations, the formation of this "intramembranous" bone in the long bones is regulated by signals from the chondrocytes, so can be thought of developmentally as part of the process of endochondral bone formation. Intramembranous bone formation also occurs during bone repair after fracture, particularly when the bones are stabilized (fixed).

KEY POINTS

- Intramembranous bone forms directly from mesenchymal condensations. Intramembranous ossification is the process used to form the bones of the calvarium and parts of the clavicle and scapula.

Endochondral Ossification

Endochondral ossification is the mechanism responsible for the formation of all long bones of the axial skeleton (vertebrae and ribs) and the appendicular skeleton (limbs). Most of the axial skeleton is derived from cells of the paraxial mesoderm that condense early in embryogenesis on both sides of the neural tube and the notochord. The appendicular skeleton arises from the lateral plate mesoderm. The mechanisms underlying the early condensation, segmentation, differentiation, and patterning events define the precise arrangement of the individual anatomic elements and their patterning along the body axes. These mechanisms involve the actions of and crosstalk among several morphogens, including fibroblast growth factors (FGFs), sonic hedgehog, bone morphogenetic proteins (BMPs), and Wnts, as well as control by Notch signaling and by transcription factors encoded by *HOX*, *PAX1*, and *TBX*.[2]

As in intramembranous ossification, the development of the long bones starts with mesenchymal progenitor cells forming condensations. In the mesenchymal condensations of endochondral bones, cells do not differentiate into osteoblasts but instead differentiate into chondrocytes that synthesize a characteristic extracellular matrix rich in type II collagen and specific proteoglycans. As such, a cartilaginous model or anlage is established that prefigures the future bone. These differentiated cartilage structures in the limb appear in sequence along the proximodistal axis (i.e., hip to toes, shoulder to fingers). The sequential steps of the endochondral ossification process starting from this stage are illustrated in Fig. 51.1. Initially, the cartilage further enlarges through chondrocyte proliferation and matrix production. Chondrocytes in the midportion of the bone model then stop proliferating, undergo further maturation, and ultimately become hypertrophic. These large hypertrophic chondrocytes secrete a distinct matrix, containing type X collagen, and then rapidly direct the calcification of the matrix. Concomitantly, the hypertrophic chondrocytes direct the cells surrounding the cartilage element called the perichondrium to differentiate into osteoblasts that deposit mineralized bone matrix—the "bone collar"—around the cartilage template. This bone collar forms the initiation site of the cortical bone,

Fig. 51.1 Stepwise Schematic Diagram of Long Bone Development Through Endochondral Ossification. Around embryonic day (E) 12 in mice, mesenchymal progenitor cells condense and differentiate into chondrocytes to form the cartilage anlagen that prefigure future long bones. Chondrocytes in the center become hypertrophic, while cells in the surrounding perichondrium differentiate into osteoblasts, forming a bone collar, the provisional cortical bone. The hypertrophic cartilage core subsequently is invaded by blood vessels along with osteoprogenitors and osteoclasts and becomes eroded and replaced by bone and marrow (primary ossification center). In the metaphysis, hypertrophic cartilage of the growth cartilage is continually replaced by trabecular bone, a process that relies on metaphyseal vascularization and mediates longitudinal bone growth (see postnatal day [P] 1). Around P5, epiphyseal vessels invade the avascular cartilage at the ends of the bone and initiate the secondary centers of ossification. Discrete layers of residual chondrocytes form growth plates between the epiphyseal and metaphyseal bone centers to support further postnatal longitudinal bone growth. Ultimately (in humans), the growth plates close, and growth stops. A detailed view of the perinatal bone structure (boxed area indicated at P1) is provided in Fig. 51.2.

the dense outer envelope of compact, lamellar bone that provides the long bone with most of its strength and rigidity (see Fig. 51.1).

At this time in development, the cartilage model starts to become replaced by bone, vascular, and marrow elements: the primary ossification center (Fig. 51.1). The transformation is initiated by the invasion of the hypertrophic cartilage core by blood vessels (around embryonic day 14 to 15 in mice) (see later). Lineage tracing genetic studies in mice have shown that, along with the invading vasculature, immature osteolineage cells coenter the developing primary ossification center, with at least a subset of them taking perivascular positions associating closely with the blood vessels.[3] This osteoangiogenic cartilage invasion is accompanied by apoptosis of terminally differentiated hypertrophic chondrocytes, resorption of the calcified cartilage matrix by invading osteoclasts or related "chondroclasts," and deposition of mineralized bone matrix on the remnants of calcified cartilage by perichondrium/periosteum-derived osteoblasts.

With the disappearance of the diaphyseal cartilage (see Fig. 51.1), the remaining chondrocytes, restricted to the opposing ends of the long bone, provide the engine for subsequent bone lengthening. This process is typified by precise temporal and spatial regulation of chondrocyte proliferation and differentiation, with the chondrocytes first flattening out and forming longitudinal columns of rapidly proliferating cells and next, as they reach the ends of the columns closest to the center of the bones, maturing further

Fig. 51.2 **Schematic View of the Cellular Structure of Developing Long Bones.** The epiphysis is composed of chondrocytes, organized in layers of proliferation (round periarticular and flat columnar proliferating cells), progressive differentiation toward the metaphysis (prehypertrophic and hypertrophic chondrocytes), and cell death (apoptosis). The avascular cartilage is supplied by the epiphyseal blood vessel network that overlays its surface. In the metaphysis, blood vessels invading the terminal hypertrophic chondrocytes, osteoclasts resorbing the cartilage, and osteoblasts building bone on the cartilage remnants all act coordinately to replace the cartilage anlagen with bone and marrow.

to hypertrophic chondrocytes (Fig. 51.2). Finally, at the border with the metaphysis, many of the terminally differentiated chondrocytes disappear through apoptosis, while a fraction of them likely evolve or transdifferentiate into bone marrow stromal cells (BMSCs) and osteoblast lineage cells (see below).[4,5] Meanwhile, the calcified hypertrophic cartilage matrix is digested by osteoclasts and progressively replaced with cancellous or trabecular bone (forming the primary spongiosa). This process of cartilage turnover and replacement by bone requires adequate neovascularization of the chondroosseous junction by metaphyseal capillaries (see Fig. 51.1 and cellular details in Fig. 51.2).[6] Thus, similar to the initial formation of the primary ossification center, endochondral bone formation at the growth cartilage involves rigorous coupling of vascular invasion with maturation and activity of chondrocytes, osteoclasts, and osteoblasts.

At a certain time (around postnatal day 5 in mice), epiphyseal vessels (Fig. 51.1) derived from the vascular network that overlays the cartilage tissue invade the growth cartilage and initiate the formation of the secondary center of ossification in larger long bones. As a result, discrete layers of residual chondrocytes form true growth plates between the epiphyseal and metaphyseal ossification centers, mediating further postnatal longitudinal bone growth. Ultimately, at least in humans, the growth plates completely disappear (close) at the end of adolescence in a process that actively requires the action of estrogen in both boys and girls, and lengthening stops. Remodeling of existing bone, replacing the primary spongiosa with lamellar bone in the secondary spongiosa and renewing the cortical bone, takes place throughout adult life, ensuring optimal mechanical properties of the skeleton and contributing to mineral ion homeostasis. This continual bone turnover is accomplished through the balanced action of osteoclasts and osteoblasts (see later and Fig. 51.3) and results in a dynamic organization of honeycomb platelike structures or trabeculae in the interior of the bone that are surrounded by blood vessels and bone marrow and housed within the cortical bone.

KEY POINTS

- Most bones form through the process of endochondral bone formation. All the cells on the inside of the mesenchymal condensations become chondrocytes that proliferate and lay down cartilage matrix. The central chondrocytes of the condensation stop dividing, become hypertrophic, and signal to allow vascular invasion, followed by osteoblast differentiation from cells associated with the blood vessels and from some chondrocytes; this establishes the primary ossification center. At the ends of long bones, chondrocytes proliferate, hypertrophy, and attract more blood vessels, leading to formation of the secondary ossification center. Chondrocytes between these centers of ossification form orderly, proliferating columns in the growth plate, leading both to bone lengthening and progressive formation of new bone from dying hypertrophic chondrocytes.

PRINCIPLES OF BONE REMODELING AND SKELETAL HOMEOSTASIS

The Bone Remodeling Cycle

Bone is constantly being renewed by undergoing a process of self-destruction followed by a regenerative process. Depending on mechanical and physiologic needs, osteoclasts resorb particular pockets of existing trabecular and cortical mineralized bone tissue, whereas osteoblasts lay down new bone at appropriate sites to replace the lost bone (Fig. 51.3). Packets of bone that are renewed during remodeling are called bone-remodeling units (BRUs) or bone multicellular units. It has been estimated that the adult human skeleton contains more than a million of these microscopic remodeling foci at any one time. The bone in an activated BRU is first removed by osteoclastic bone resorption through a process that takes a few weeks (see Fig. 51.3). Lost bone is replaced by osteoblastic bone formation, lasting 3 to 4 months for one packet. This discrepancy in the kinetics of bone resorption and formation explains in part how increased resorption, even when accompanied by coupled increased formation, can cause bone loss, for example, in estrogen deficiency or hyperparathyroidism.

How the bone resorption that starts the remodeling cycle itself is initiated remains enigmatic but may involve osteoblast lineage cells perceiving and responding to a remodeling signal by regulating osteoclast formation (see later). The mechanisms that regulate the recruitment of the hematopoietic precursors for the osteoclasts to the bone environment and the remodeling sites are also not very clear, although several findings indicate that the lipid mediator sphingosine-1-phosphate (S1P) may be involved in regulating their movement between the circulation and the bone marrow.[7] Osteoclast precursors, which highly express the S1P receptor 1 (S1PR1), appear to be attracted from the marrow to the bloodstream under physiologic conditions by S1P, whose concentration is higher in blood than in marrow. Conversely, the receptor S1PR2 appears to have a reciprocal function, mediating the attraction of the cells from the bloodstream to remodeling sites. Mice with deletion of *S1PR1* in osteoclast precursors developed excessive bone resorption and osteoporosis because the cells remain in the marrow and differentiate into osteoclasts; mice with deficiency in *S1PR2*, on the other hand, have moderate osteopetrosis owing to reduced bone resorption, because their osteoclast precursors remain in the bloodstream.[7,8]

The signal responsible for the completion of resorption in a remodeling cycle also has not been determined *in vivo*, but several factors that reduce osteoclast formation or activity could play a role (see later). In healthy bones, cessation of resorption is followed by bone formation. During the time lag that occurs between the end of resorption and the beginning of formation, called the reversal phase, small cells are seen on the resorbed surface, perhaps osteoblast precursors that are attracted to the BRU. At this stage of the remodeling cycle, plump cuboidal osteoblastic cells differentiate on the bone surface and deposit the organized matrix, which then becomes mineralized. The bone formation period is completed after approximately 4 months, when the respective packet of bone, either on the surface of a trabeculum or in the cortical haversian canal system, enters a quiescent period until the next remodeling cycle (see Fig. 51.3).

KEY POINTS

- Bone is constantly turning over in an orderly process undertaken by groups of cells called a bone multicellular unit. Probably initiating when osteoblast lineage cells sense microdamage or mechanical forces, signals including sphingosine-1-phosphate draw hematopoietic precursors from the bloodstream that form osteoclasts that then home to the site of injury. Bone resorption over several weeks is followed by a reversal phase with less active bone resorption, followed by several months of bone formation in the region where matrix had been removed by osteoclasts. In this complicated process, cells of the osteoblast and osteoclast lineages differentiate and signal to each other to coordinate the removal and new formation of bone.

Unbalanced Bone Remodeling in Metabolic Bone Diseases

Bone remodeling must be tightly controlled to maintain normal bone homeostasis. Failure of this normal skeletal functioning is one of the most common early manifestations of aging, for example, in osteoporosis and osteoarthritis. These and a variety of other pathologic conditions affecting the skeleton (e.g., rheumatoid arthritis, periodontitis, Paget disease, bone tumors) lead to perturbations in the bone remodeling process, predominantly shifting the balance toward increased degradation of bone owing to local and/or systemic alterations in the levels of hormones or

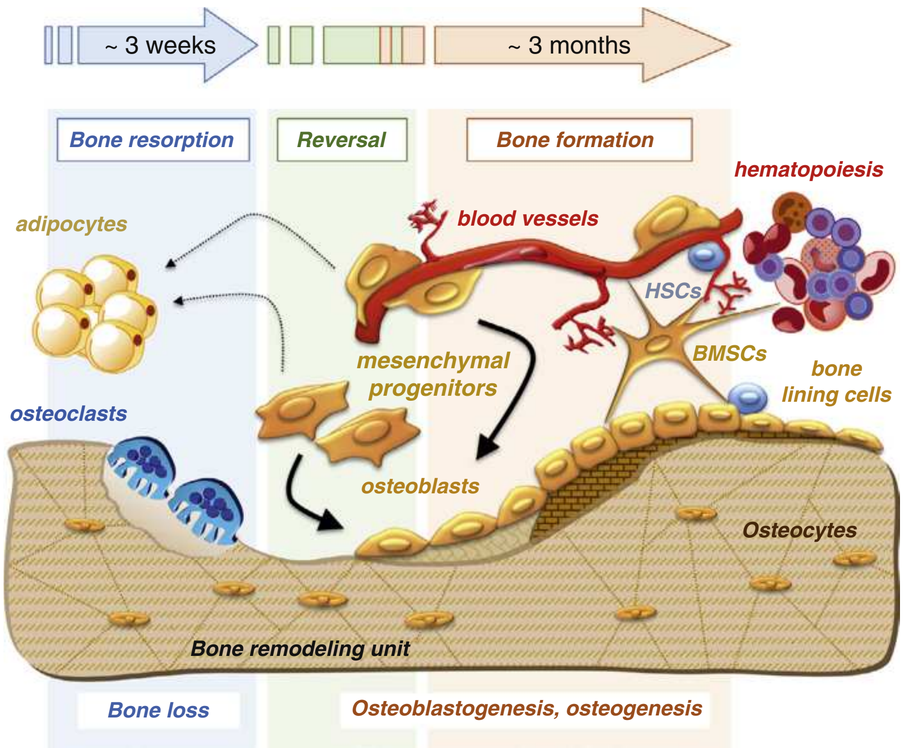

Fig. 51.3 Three-Phase Model of Bone Remodeling. The skeleton is a metabolically active organ that undergoes continuous remodeling throughout life in bone remodeling units. Bone remodeling involves the removal of mineralized bone by osteoclasts, followed by the formation and subsequent mineralization of bone matrix by osteoblasts. The remodeling cycle starts with recruitment of hematopoietic precursors and their differentiation to osteoclasts, induced by osteoblast lineage cells that express osteoclastogenic ligands such as receptor activator of nuclear factor-κB ligand. Osteoclasts become multinucleated and resorb bone. Reversal is marked by switching from bone resorption to bone formation; this is mediated by coupling factors, which can stimulate mesenchymal progenitor recruitment, osteoblast differentiation, and/or cellular activity. During the bone formation phase, the resorbed lacuna is refilled through osteogenesis by osteoblasts that later flatten to form a layer of lining cells on the bone surface or become osteocytes connected by canaliculi within the bone. The process of bone remodeling stands in close relationship with the skeletal vascularization and involves interplay with various cell types in the highly heterogeneous bone and bone marrow environment, including populations of perivascular and reticular bone marrow stromal cells, which can give rise to osteoblasts or marrow adipocytes, as well as form niches for hematopoietic stem cells and support hematopoiesis. *BMSC,* bone marrow stromal cell; *HSC* hematopoietic stem cell.

proinflammatory cytokines that stimulate bone resorption (see later). In cancellous bone, the loss results in thinner trabeculae and in trabecular discontinuity. In cortical bone, endosteal bone resorption causes thinning and sometimes trabecularization of the cortex, increasing the porosity of the cortical bone. The result of these changes is significant weakening of the bones. Osteoporosis, characterized by low bone mass and high risk for debilitating fractures of the vertebrae and long bones, afflicts millions of people, particularly postmenopausal women, and becomes increasingly prevalent with the aging of the general population. Estrogen deficiency increases both the number of sites at which remodeling is initiated and the extent of resorption at a given site (see later). Increased bone resorption is accompanied by increased bone formation as a result of signals that couple these processes (see later). However, the increase in bone formation is not sufficient to maintain bone balance and prevent bone loss.

KEY POINTS

- In metabolic bone disease, the balance between bone resorption and formation is disrupted. A variety of stimuli, for example, those unleashed by estrogen deficiency or aging, trigger an increase of osteoclastic bone resorption, while at the same time defects in bone formation can fail to keep up with the osteoclastic bone loss. The result in trabecular bone is thinning and decrease in number of trabeculae, and in cortical bone a decrease in the amount of cortical bone and increased cortical porosity.

CELLULAR AND MOLECULAR CONTROL OF SKELETAL DEVELOPMENT AND BONE REMODELING

Here, we will review some of the principal growth and transcription factors and signaling cascades known to affect key aspects of bone development and maintenance.

Chondrogenesis and Growth Plate Biology

A crucial step in endochondral bone development entails the differentiation of cells in the mesenchymal condensations into chondrocytes. Some of the mesenchymal cells are osteochondroprogenitor cells with the potential to differentiate into chondrocytes or osteoblasts. The decision to follow a given differentiation pathway is determined by the expression of key transcription factors, likely under the influence of canonical Wnt signaling.[9] As will be discussed in greater detail later, Wnt signaling results in the stabilization of β-catenin, which then can act as a transcription factor and regulate the expression of downstream target genes. Several studies using genetic modifications in mice have provided evidence that in the fetal perichondrium, where cells are destined to become osteoblasts, Wnt signaling is high (at least in part induced by Indian hedgehog [Ihh]), leading to high levels of β-catenin and inducing the expression of factors that mediate osteoblast differentiation (such as runt-related transcription factor 2 [Runx2], a master regulator of osteoblastogenesis, see later), while inhibiting transcription of genes required for chondrocyte differentiation (such as *Sox9*). In the absence of β-catenin during embryonic bone development, these cells become chondrocytes instead of osteoblasts; conversely, in the inner region of the condensations, Wnt signaling must be low in order for these cells to become chondrocytes.[9] The initial conversion of mesenchymal progenitor cells into chondrocytes is driven by the transcription factor Sox9, whereas the combined action of Sox9, 5, and 6 is required to direct the subsequent differentiation of chondrocytes throughout all phases of the chondrocyte lineage.[10]

In the growth cartilage, the most extensively studied cartilage, differentiation of committed cells along the chondrocyte lineage characteristically gives rise to a stratified organization of small, round periarticular chondrocytes (also previously termed resting, or reserve chondrocytes, because these cells proliferate only slowly after birth and can become columnar chondrocytes), flattened, columnar proliferating chondrocytes, and prehypertrophic and hypertrophic chondrocytes (see Figs. 51.2 and 51.4). Because progression of the chondrocytes through these stages is the driving force of actual bone development and growth, it is not surprising that the process is tightly controlled by a myriad of local signaling molecules, the best characterized being BMPs and transforming growth factor-β (TGFβ), FGFs, parathyroid hormone (PTH)-related protein (PTHrP), and Ihh. The importance of these molecules is reflected by the fact that mutations in their receptors have been found to cause severe human dwarfing conditions, such as constitutive activating mutations of FGF receptor (FGFR) 3 in human achondroplasia and thanatophoric dysplasia[11,12] and PTH/PTHrP receptor mutations in Jansen and Blomstrand chondrodysplasia.[13] Here, we will briefly review the basic mechanisms by which these signaling systems control the pace of proliferation and differentiation of growth chondrocytes.

BMPs, secreted proteins belonging to the TGFβ superfamily, transduce signals through serine/threonine kinase receptors, which are homomeric or heteromeric complexes composed of type I and type II receptor subtypes. The ligand binding activates intracellular proteins of the Smad family that relay the BMP signal to target genes in the nucleus. BMPs were first discovered as agents in bone matrix capable of inducing ectopic formation of cartilage and bone after injection into subcutaneous tissues. Subsequent studies have shown that BMPs, some of which are also called growth and differentiation factors, are, in fact, signaling proteins crucial for regulating development in almost all the principal organs and tissues. In the morphogenesis of the skeleton, BMPs have been implicated most strongly in early limb patterning, as well as in the subsequent processes of chondrogenesis and osteogenesis (also see further) (Fig. 51.4).[14]

The FGF pathway similarly involves multiple ligands and receptors in regulating skeletal development.[12] FGF18 and FGF9 are the most important FGF ligands in regulating chondrogenesis identified so far. These ligands activate FGFR3 expressed on proliferating chondrocytes (Fig. 51.4). Activating mutations in the *FGFR3* gene cause dominantly inherited human dwarfing chondrodystrophies because of impaired chondrocyte proliferation,[11] and FGFR3 inactivation in mice increases chondrocyte proliferation and prolongs growth.[12] This finding was

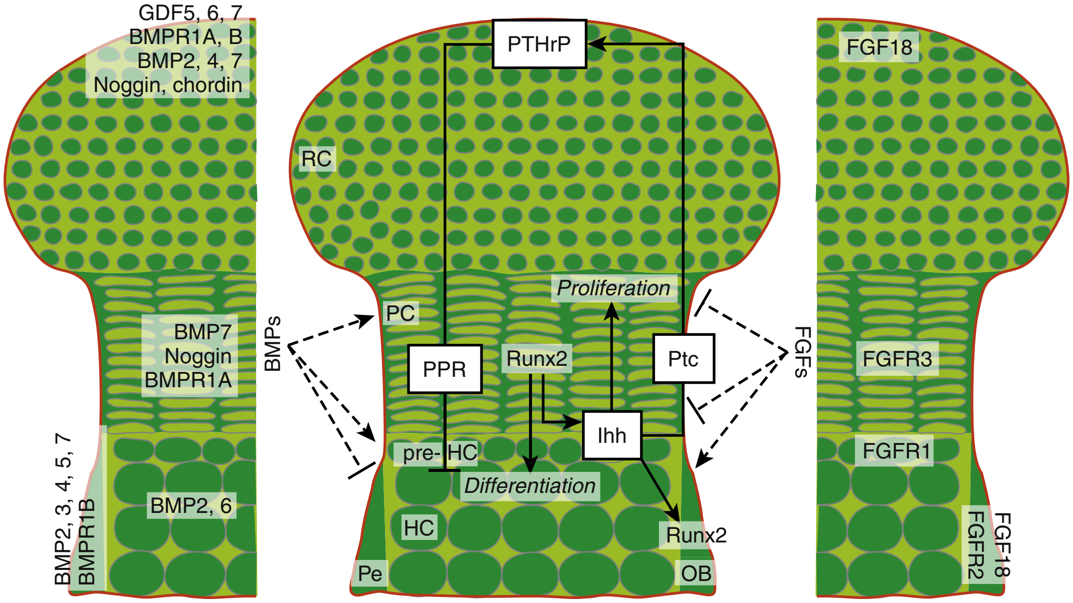

Fig. 51.4 Regulation of Chondrocyte Proliferation and Differentiation. Schematic representation of the epiphysis, with zones of periarticular round chondrocytes (*RC*), strongly proliferating columnar chondrocytes (*PC*), and (pre-)hypertrophic chondrocytes ([pre-]HC). Hypertrophic cartilage is surrounded by perichondrium (Pe), where osteoblasts (*OB*) develop. Centrally, the Indian hedgehog (Ihh)/parathyroid hormone-related protein (PTHrP) negative feedback loop is indicated. Cells at the articular end of the bone secrete PTHrP, acting through the PTH/PTHrP receptor (*PTHR1* or *PPR*) on columnar chondrocytes to keep them in the proliferating pool and delay their differentiation. When the distance from the bone end becomes sufficiently large, cells escape the differentiation block and become Ihh-expressing prehypertrophic chondrocytes. In an as yet unknown manner, Ihh induces PTHrP expression. In addition, Ihh directly stimulates chondrocyte proliferation and converts perichondrial cells into OBs by inducing runt-related transcription factor 2 (*RUNX2*), thereby determining the site of bone collar formation. RUNX2 also favors Ihh expression and hypertrophic differentiation. Several bone morphogenetic protein (*BMP*) and fibroblast growth factor (*FGF*) family members are expressed at specific sites in the growth cartilage (left and right panels). BMPs and FGFs act antagonistically to modulate chondrocyte proliferation, Ihh expression, and terminal hypertrophic differentiation. *GDF*, Growth and differentiation factor; *Ptc*, patched; *BMPR,* BMP receptor; *FGFR*, FGF receptor.

surprising, given that FGFs in most tissues act as potent mitogens; although this may pertain in early chondrogenesis, in which FGF18 stimulates proliferation, later in development signaling through FGFR3 constitutes a master block on chondrocyte proliferation through activation of STAT1, which activates the cell cycle inhibitor p21$^{Waf1/Cip1}$.[12] In addition, although previous *in vitro* experiments had indicated that FGF signaling accelerates the late steps of chondrocyte hypertrophy, mouse models of achondroplasia and thanatophoric dysplasia have shown delayed hypertrophic differentiation of chondrocytes, strongly suggesting that FGFR3 signaling *in vivo* inhibits chondrocyte differentiation.[12] This effect is relayed by activation of the mitogen-activated protein kinase (MAPK) pathway in chondrocytes, which affects longitudinal growth by regulating hypertrophic chondrocyte differentiation and matrix deposition.

A major regulatory system in growth chondrocytes is provided by Ihh, a member of the conserved family of hedgehog proteins, and by PTHrP.[13] The Ihh/PTHrP pathway forms a negative feedback loop that regulates the onset of hypertrophic differentiation (see Fig. 51.4). Hedgehog proteins, upon binding to the Patched (Ptc) receptor, signal through the seven-pass transmembrane protein Smoothened to regulate gene transcription through both derepression and activation of the Gli family of transcription factors. Ihh is produced by prehypertrophic and early hypertrophic chondrocytes and signals through Ptc to stimulate expression of PTHrP by chondrocytes located near the periarticular ends of bone. Increased production of Ihh leads to increased PTHrP production. PTHrP in turn signals back to its receptor PTHR1—the PTH/PTHrP receptor that also responds to PTH in osteoblasts and kidney—that is expressed at low levels by proliferating chondrocytes and at high levels by prehypertrophic cells. This signaling slows down chondrocyte differentiation and keeps chondrocytes in the proliferative state (see Fig. 51.4). This slowed differentiation consequently delays the generation of cells that can produce Ihh; therefore, the production of PTHrP is lowered. Thus, a negative feedback signaling pathway allows PTHrP and Ihh to regulate each other and, in turn, to control the pace of chondrocyte development in the growth plate.[13,15,16] It is important to note that the phenotype of *Ihh*$^{-/-}$ mice[17] revealed that Ihh has additional functions in endochondral bone formation, independent of regulation of PTHrP production. Indeed, these mutant mice also displayed a marked decrease in chondrocyte proliferation and absence of mature osteoblasts and bone collar formation.[17] The regulation of chondrocyte proliferation represents a direct action of Ihh signaling to chondrocytes. Ihh also accelerates the conversion of round periarticular chondrocytes to flat columnar chondrocytes. Moreover, Ihh (together with other, yet unidentified effectors) stimulates the expression of Runx2 in perichondrial cells. Under the influence of this essential transcription factor for osteoblast development (see later), the perichondrial cells are driven into the osteoblast lineage; hence, Ihh-induced direct actions also provide control of bone collar formation. Further, Runx2 in chondrocytes regulates Ihh expression and also regulates further chondrocyte differentiation into the hypertrophic stage, as revealed by chondrocyte maturation abnormalities in *Runx2*-null mice and conditional mutants deleting or overexpressing *Runx2* in cartilage.[18] Thus, it is evident that Ihh is a master regulator of endochondral bone development, coordinating chondrocyte proliferation, chondrocyte maturation, and osteoblast differentiation (see Fig. 51.4). A continued role for both PTHR1 and Ihh in the postnatal growth plate has been revealed by employing inducible mutagenesis in mice; inactivation of either gene in juvenile mice led to premature closure of the growth plate.[19,20]

Each of these pathways mentioned previously has multiple mechanisms for communicating with each other as they regulate chondrocyte and osteoblast differentiation.[21] Moreover, aside from these factors, chondrogenesis is affected by several other growth factors, cytokines, and hormones, including growth hormone (GH) and insulin-like growth factors (IGFs), C-natriuretic peptide, retinoids, thyroid hormone, estrogen, androgen, 1,25-dihydroxyvitamin D_3 [$1{,}25(OH)_2D_3$], glucocorticoids, and others.

In addition, importantly, the chondrocytes in the cartilage templates and growth plates of the endochondral bones typically develop over a prolonged period in the absence of blood vessels. As an avascular tissue, cartilage consequently faces the challenge of hypoxia.[22] The main mediator of cellular responses to hypoxia is the transcription factor hypoxia-inducible factor (HIF)-1.[23] HIF-1 consists of two subunits, HIF-1α and HIF-1β. HIF-1β is constitutively expressed in an oxygen-independent manner, while HIF-1α is activated only in hypoxic conditions (when oxygen levels drop to <5%). In conditions of higher oxygen tension, a class of 2-oxoglutarate–dependent and iron-dependent prolyl hydroxylases modify HIF-1α such that the protein becomes recognized by the von Hippel Lindau protein and targeted for destruction by this ubiquitination complex. The half-life of HIF-1α is consequently very short. Hence, specifically under hypoxic conditions, HIF-1α can accumulate, translocate to the nucleus, dimerize with HIF-1β, and bind to hypoxia response elements within the promoters of hypoxia-responsive genes.[22,23] To date, more than 100 putative HIF-1 target genes have been identified that are involved in a variety of biological processes; primary roles of HIF-1 transcriptional activity are induction of anaerobic metabolism (for instance, by regulating glycolytic genes), angiogenesis (through induction of vascular endothelial growth factor [VEGF]), and erythropoiesis (via increased erythropoietin expression).[23]

HIF-1α is absolutely essential for the survival and controlled differentiation of hypoxic chondrocytes: mice with conditional inactivation of HIF-1α displayed aberrant apoptosis of chondrocytes located in the center of the growth cartilage, farthest from blood vessels.[24] In addition, HIF-1α influences the cartilaginous matrix, such as by improving the efficiency of posttranslational modifications of type II collagen.[25] The mechanisms by which HIF-1 ensures the survival of hypoxic chondrocytes include the direct activation of genes that enable chondrocytes to switch to oxygen-sparing metabolic pathways, as well as the indirect consequences of induction of VEGF.[22,24] Deletion of *Vegf* from cartilage also results in massive apoptosis of nonhypertrophic, hypoxic chondrocytes located in the center of the growth plate, which could point at a cell-autonomous survival function effected by VEGF on chondrocytes. Alternatively, or additionally, VEGF expression in proliferating chondrocytes (in response to hypoxia and/or HIF-1) seems critical for stimulating vascularization in the immediate surroundings of the cartilage, thereby ensuring sufficient oxygen diffusion to the avascular cartilage to prevent cell death.[22] In addition to regulating blood vessel formation in the perichondrium, VEGF also induces blood vessel invasion and growth within the endochondral bones during skeletal development and growth, as discussed next.[6,26]

KEY POINTS

- Many paracrine factors and transcription factors regulate the survival, proliferation, and differentiation of growth cartilage. Bone morphogenetic proteins drive the generation of chondrocytes from mesenchymal cells and also their further proliferation and differentiation. Indian hedgehog (Ihh), made by prehypertrophic chondrocytes, directly stimulates the proliferation of adjacent chondrocytes and also stimulates the production of parathyroid hormone–related protein (PTHrP); PTHrP keeps chondrocytes proliferating. Ihh, along with subsequent Wnt signaling, also directs adjacent perichondrial cells to become osteoblasts. Perichondrial cells secrete fibroblast growth factors (FGFs) that activate FGF receptor 3 (FGFR3) on chondrocytes; this action slows the proliferation and differentiation of chondrocytes. Constitutively active mutations of FGFR3 lead to achondroplasia, a disease of short stature. Hypoxia inducible factor (HIF) is crucial for directing the metabolism of chondrocytes in the avascular growth plate and also induces the synthesis of vascular endothelial growth factor (VEGF).

Skeletal Vascularization

Both temporally and spatially, chondrocyte differentiation is followed by vascular invasion of the terminally differentiated, hypertrophic cartilage. This step is an absolute requirement for endochondral bone development and growth to proceed, as physical blockage of blood vessel invasion into the hypertrophic cartilage of fetal skeletal explants completely halts their development, and blocking the blood supply of bone *in vivo* results in reduced longitudinal growth.[6,26] During endochondral ossification, the initially avascular cartilage template is replaced by highly vascularized bone and marrow tissue through three consecutive vascularization events (see Figs. 51.1 and 51.5).[21,26] First, initial vascular invasion of the cartilage anlagen during embryonic development (sometimes called quiescent angiogenesis) involves endothelial cells invading from the perichondrial tissues and organizing into immature blood vessels in the primary center of ossification. Second, capillary invasion at the metaphyseal border of the growth cartilage is required for rapid bone lengthening (see Figs. 51.1, 51.2, and 51.5). Third, vascularization of the cartilage ends initiates the formation of secondary ossification centers (see Figs. 51.1 and 51.5). Hence, a process of cartilage neovascularization initiates each of the subsequent stages of endochondral replacement of cartilage by bone; at all times, this cartilage neovascularization is preceded by chondrocyte hypertrophy. Immature chondrocytes produce angiogenic inhibitors, such as chondromodulin-I and troponin-I, rendering the cartilage resistant to vascular invasion. In contrast, when chondrocytes become hypertrophic, they switch to production of angiogenic stimulators, including the potent angiogenic stimulator VEGF, and become a target for capillary invasion and angiogenesis. VEGF is expressed at very high levels by hypertrophic cartilage, as well as by osteoblasts and osteoclasts. Hypoxia represents a crucial trigger of VEGF expression in chondrocytes, osteoblasts, and possibly osteoclasts, through mechanisms that involve HIF both *in vitro* and *in vivo*. VEGF transcription may also be induced by Runx2 and by Osterix (Osx) (see later). In addition, several hormones (including PTH, GH, and 1,25$(OH)_2D_3$) and locally produced growth factors (e.g., FGFs, TGFβ, BMPs, IGFs, platelet-derived growth factor [PDGF]) have been demonstrated to be involved, at least *in vitro*, in the regulation of VEGF expression.[26]

Mouse genetic studies have demonstrated multiple essential roles of VEGF and its splice isoforms in endochondral ossification. Although ablation of one or both *Vegf* gene alleles in all cells causes early lethality in mice, several alternative mutagenesis approaches have been developed to investigate the role of VEGF in bone. These models include Cre/LoxP-mediated conditional inactivation of the *VEGF* gene (*VEGFa)* in type II collagen–expressing chondrocytes or in Osx-expressing osteoprogenitors, inactivation of two of the three major VEGF isoforms (leaving expression of only one isoform), and skeletal tissue-specific overexpression of VEGF in genetically engineered mice (reviewed in Maes[26]). These models demonstrated that VEGF is a key inducer of all three key vascularization stages of endochondral bone development (Fig. 51.5), but also acts as a direct modulator of bone development by affecting various cell types. Perichondrial cells, osteoblasts, and osteoclasts express VEGF receptors and respond to VEGF signaling through enhanced recruitment, differentiation, activity, and/or survival (for detailed reviews and references, see Maes [21,26]). In most of these functions, VEGF works in paracrine mode, but intracrine VEGF effects in (Osx-expressing) osteoprogenitors have also been reported, determining cell fate decisions in these cells; in the absence of intracellular VEGF signaling, the cells differentiated into adipocytes rather than osteoblasts.[27] Altogether, the pleiotrophic actions of VEGF on various bone cells contribute to the tight coordination of vascularization, ossification, and matrix resorption needed for endochondral ossification.

The prevailing model for VEGF action in endochondral bone development is as follows (Fig. 51.5): VEGF is secreted at particularly high levels by hypertrophic chondrocytes. VEGF is partially soluble (the short VEGF isoforms) and partially bound to constituents in the cartilage matrix (the long isoforms), from where it is further released as the terminal cartilage undergoes progressive decay in the endochondral turnover process. VEGF attracts blood vessels toward the chondroosseous junction and stimulates endothelial cells to form new blood vessels (angiogenesis), which will be indirectly associated with increased delivery of osteoblast and osteoclast progenitors.[26] At the same time, VEGF signaling directly stimulates the recruitment and differentiation of osteoblasts to form bone.[28] VEGF also works as a chemoattractant stimulating osteoclast invasion of cartilage, and enhances osteoclast differentiation, survival, and resorptive activity.[29] This likely activates a positive feedback system, as increased osteoclasts and osteoclast-derived matrix metalloproteinase (MMP) 9[30] can release more matrix-bound VEGF from the cartilage that is being resorbed (Fig. 51.5).[21,26]

The skeletal vascular system remains a vitally important player in the regulation of bone health beyond development and growth. Optimal tissue vascularization is essential for adequate homeostatic bone remodeling, and bone fracture repair and regeneration critically rely on revascularization of the injury site. In fact, any type of bone formation during growth, homeostasis, disease, or repair occurs in close spatial and temporal association with vascularization of the ossified tissue, a principle termed angiogenic-osteogenic coupling.[31] The vascular system is crucial, through its intrinsic function to supply oxygen, nutrients, and growth factors/hormones to bone cells as required for their specified activities. In addition, the blood vessels serve to bring in (precursors of) osteoclasts that will degrade the cartilage or bone extracellular matrix, to remove endproducts of the resorption processes, and to bring in progenitors of osteoblasts that will deposit bone.[3,26,31] Hypoxia-driven pathways, including HIF and VEGF signaling, and the Notch pathway represent major regulators of angiogenic-osteogenic coupling in postnatal bone remodeling and ageing.[22,32,33]

KEY POINTS

- Vascular endothelial growth factor (VEGF), secreted from hypertrophic chondrocytes, is essential for attracting the blood vessels and osteoblast precursors that generate the primary and secondary ossification centers. VEGF acts on receptors on the surface of endothelial cells and cells of the osteoblast lineage to direct their mobility, proliferation, and differentiation, and VEGF also attract osteoclasts. Hypoxia-inducible factor (HIF)-1α and various paracrine factors direct the synthesis of multiple spliced isoforms of VEGF.

Skeletal Stem and Progenitor Cells

Considerable progress has been made recently in the identification in both mice and humans of populations of skeletal stem cells (SSCs) and SSPCs, an overarching inclusive term encompassing bone fide SSCs as well as tri/bipotent and lineage-committed osteogenic progenitor cells (Fig. 51.6). SSCs have been identified in the growth plate and the fetal perichondrium and postnatal periosteum, as well as among the reticular and perivascular mesenchymal stromal cells dispersed throughout the bone marrow[34-41] (also see Fig. 51.3). They have the ability to give rise to cells of the prime skeletal lineages—osteoblasts, chondrocytes, and marrow adipocytes (fat cells)—with each of the distinct cell fate decisions and differentiation processes being driven by lineage-specific transcription factors (as indicated in Fig. 51.6).[42] BMSCs include a variety of osteogenesis-competent SSPC populations characterized by the expression of specific

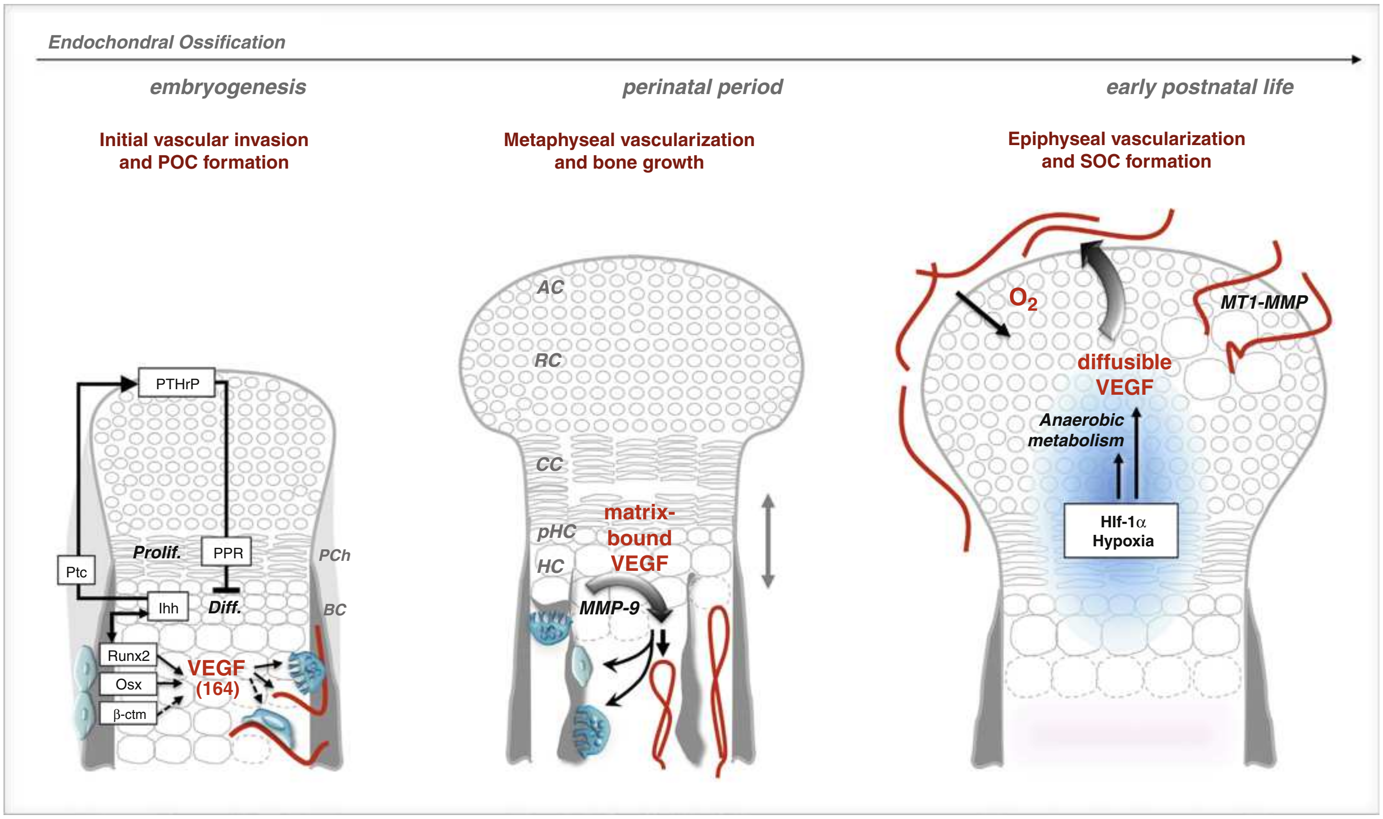

Fig. 51.5 Vascular Invasion During Endochondral Bone Development and the Role of Vascular Endothelial Growth Factor (*VEGF*). *Left panel,* During embryogenesis, the initiation of cartilage neovascularization is coordinated with proliferation and differentiation of chondrocytes in the avascular anlagen, osteoblastogenesis and bone collar (BC) formation in the surrounding perichondrium (PCh), and the expression of high levels of VEGF by hypertrophic chondrocytes in the middle portion of the bone model. Invasion by blood vessels is accompanied by chondrocyte apoptosis, osteoclastic cartilage resorption, and coinvasion by osteoprogenitors moving to the inside of the nascent primary ossification center (*POC*). For details on the molecular regulators, see text. *Middle panel,* Longitudinal bone growth is driven by the progressive replacement of cartilage with trabecular bone, a process that relies on metaphyseal vascularization mediated by VEGF. VEGF is produced at high levels by hypertrophic chondrocytes (*HCs*) and is sequestered in part in the cartilage matrix upon its secretion. Trapped VEGF can be released from the matrix by proteases such as matrix metalloproteinase (*MMP*)-9 secreted by osteoclasts/chondroclasts during cartilage resorption. VEGF then can bind to its receptors (*VEGFRs*) on endothelial cells and stimulate the guided attraction of blood vessels to invade the terminal cartilage. Osteoblasts and osteoclasts also express VEGF receptors, and VEGF can affect their differentiation and function both directly and indirectly by enhancing metaphyseal vascularization, thus playing a coordinative role in the key events that mediate bone development and growth. *AC,* Articular chondrocytes; *RC,* round chondrocytes; *CC,* columnar chondrocytes; *pHC,* prehypertrophic chondrocytes). *Right panel,* When the avascular cartilage exceeds a critical size during growth, the middle of the growth plate becomes hypoxic, stabilizing hypoxia-inducible factor (*HIF*)-1 and triggering VEGF expression in immature chondrocytes. Soluble VEGF isoforms are critical to diffuse to the surface of the cartilage, stimulating growth of the epiphyseal vascular network and tissue oxygenation. HIF-1 is additionally essential for chondrocyte survival by inducing oxygen-sparing anaerobic metabolism in the hypoxic cells. In early postnatal life, epiphyseal vessels invade the avascular cartilage and initiate a secondary center of ossification (*SOC*). (Reproduced from Maes C. Role and regulation of vascularization processes in endochondral bones. *Calcified Tissue Int.* 2013;92:307–323.)

markers, including CD146 in humans and leptin receptor, C-X-C motif ligand 12 (“CAR cells”), PDGFRβ, or PDGFRα and Sca-1 (“PαS” cells), among others, in mice.[34-36,43] Marker-based identification enables researchers to visualize the dedicated cell populations in the heterogeneous bone and bone marrow environment and isolate them for detailed studies, using advanced imaging, *in vivo* lineage tracing, flow cytometry, and high-resolution bulk and single-cell RNA sequencing technologies. These tools have also been providing new insights into the relationships among the cell lineages in bone, including the reactivation of quiescent bone lining cells upon bone anabolic stimuli such as intermittent PTH or antisclerostin antibody treatments,[44-46] adipogenic differentiation of presumed committed osteolineage cells, and transdifferentiation of hypertrophic chondrocytes into osteoblasts[4,5,47] (Fig. 51.6).

Functionally, besides providing pools of reserve cells for osteoblast differentiation and osteogenesis during homeostatic bone remodeling and fracture repair, SSPC populations in the bone marrow environment also critically support hematopoiesis by constituting functional niches regulating the maintenance and differentiation of hematopoietic stem cells (reviewed in Pinho & Frenette[48] and Crane et al.[49]). The existence of a perivascular niche for SSPCs, residing around bone marrow arteries, arterioles, and sinusoids may

Fig. 51.6 Differentiation of Skeletal Stem and Progenitor Cells (*SSPCs*) Into the Prime Skeletal Cell Lineages, With A Focus on Osteoblasts. Within the skeleton, various populations of skeletal stem cells (*SSCs*) and SSPCs exists in distinct locations. In endochondral bones SSCs have been identified in the fetal perichondrium, in the cartilaginous growth plate during the intense growth spurt of perinatal and juvenile mice, and in the bone marrow (*BM*) and periosteum during postnatal life, including adult bone homeostasis and fracture repair settings. The BM further harbors diverse SSPC populations that can give rise to osteoblasts, adipocytes, stroma, and/or chondrocytes, collectively designated BM stromal cells (*BMSCs*). The heterogeneous SSPC populations in the bone and BM environment appear to include reticular stromal cells, perivascular cells, osteochondroreticular cell progenitors, and more restricted bipotent progenitors with osteochondral differentiation potential (particularly important intermediate cells in fetal development) or osteoadipogenic capacities (found in postnatal bone). Lineage differentiation of the multipotent mesenchymal precursors into the three major skeletal lineages is controlled by respective sets of transcription factors as indicated. For osteolineage specification and differentiation, the actions of RUNX2, Osx and β-catenin are crucial. Progressive osteoblast differentiation is characterized by changes in gene expression typifying specific stages or subsets of osteolineage cells as indicated (*orange*). Mature osteoblasts ultimately undergo apoptosis, flatten to form a layer of bone lining cells on the bone surface, or become embedded within the bone as osteocytes. Recent studies indicate that, in addition to the classical, lineage-committed osteoprogenitors, hypertrophic chondrocytes may also constitute a source of osteoblasts during development and growth. In addition, quiescent bone lining cells can convert into mature osteoblasts in postnatal bone upon induction of active bone formation. Lastly, some populations of osteoprogenitors may also revert to an adipogenic differentiation state. (Reproduced from Mesnieres M, Maes C. Osteoblast lineage stem and progenitor cells. In: Zaidi M, ed. *Encyclopedia of Bone Biology. Section: Osteoblast Biology*. Oxford: Academic Press; 2020:383–396.)

also relate to the absolute necessity of blood vessels for bone formation and regeneration, a concept known as angiogenic-osteogenic coupling (see earlier).[22,33] Finally, SSPC cell fate decisions favoring adipogenesis can result in excessive bone marrow adipose tissue (BMAT) accumulation, as for instance seen with aging and pathophysiological conditions such as obesity, but also anorexia nervosa, bone trauma with marrow disruption, and cancer therapies such as irradiation and chemotherapy. Besides possibly shifting precursor cells away from osteoblastogenesis, leading to reduced bone formation, BMAT itself is thought to play a role in the skeletal contributions to systemic energy metabolism and glucose homeostasis and to affect hematopoiesis.[50,51]

KEY POINTS

- Investigators have identified cells in the bone marrow, perichondrium/periosteum, and growth plate that can form colonies *in vitro* and can differentiate into osteoblasts, chondrocytes, and adipocytes. These properties are those expected of stem/progenitor cells in bone. More recently, these studies have been combined with lineage tracing technology *in vivo*, along with single-cell sequencing and cell sorting technologies, to bring molecular rigor to the still-evolving characterization of skeletal stem and progenitor cells (SSPCs).

Osteoblastogenesis

A key step required to rebuild cartilage to bone during development consists of the differentiation of osteoblasts and the deposition of mineralized bone tissue by this specialized cell type (see Figs. 51.3 and 51.6). As outlined earlier, osteoblasts are mesenchymal cells that can descend from various SSPC populations that have the capacity to differentiate into osteoblast lineage cells through the expression of β-catenin, Runx2, and Osx; these transcription factors will be discussed in detail.[18,52,53]

Committed preosteoblasts further differentiate into mature osteoblasts, cuboidal cells on the bone surface that secrete large amounts of type I collagen and other matrix components, which together are called osteoid. Subsequently, osteoblasts direct the mineralization of the osteoid in a process that requires active alkaline phosphatase, expressed on the osteoblast membrane. These mature osteoblasts express characteristic genes, including the gene encoding osteocalcin. Ultimately, the cells die through apoptosis, are converted into thin, quiescent bone lining cells, or become embedded within the bone matrix as osteocytes. Osteocytes are found dispersed throughout the bone matrix and have the potential to live as long as the organism itself. In fact, osteocytes are the most abundant cell type in bone, constituting over 90% of adult bone cells.[54,55] As osteoblasts become encased by the mineralized bone matrix that they themselves synthesized, they dramatically change their shape, sending out numerous dendritic processes that run inside lacunar canaliculi. These processes allow osteocytes to communicate with each other, with the vasculature, and with cells on the bone surface.[55] Osteocytes are well positioned to sense and respond to mechanical forces, and a growing body of evidence documents that osteocytes mediate the actions of mechanical forces to increase bone mass (see later).[54-56] Osteocytes synthesize a series of proteins unique to this most differentiated member of the osteoblast lineage. These include dentin matrix protein 1, matrix extracellular phosphoglycoprotein, and FGF23, secreted proteins involved in systemic phosphate homeostasis, and sclerostin (SOST), an inhibitor of Wnt action (see later).[54] Through their actions to regulate bone resorption and formation, as well as phosphate and calcium homeostasis, osteocytes play a central role in the determination and maintenance of bone structure and function (see later).

A number of crucial transcription factors and signaling pathways determining osteoblastogenesis have been identified, and at least some of those play a role in inherited human bone disease.[18,52,53]

Wnt/β-Catenin Signaling. Wnts are a large family of secreted growth factors (19 different members in mouse and human genomes) that play essential roles in multiple developmental processes. Wnts are also required for adult tissue maintenance, and perturbations in Wnt signaling can lead to tumor formation and other diseases.[57] In the skeletal system, mutations in Wnt signaling components lead to skeletal malformations and diseases such as osteoporosis-pseudoglioma and osteoarthritis.

Wnts can transduce their signals through several different downstream signaling pathways. The best understood pathway is the canonical or Wnt/β-catenin pathway.[57] Central to this pathway is the regulation of the protein stability of β-catenin, which acts as a transcription factor in the canonical Wnt pathway and is also involved in cell adhesion by binding to cadherins. In the absence of Wnts, cytoplasmic β-catenin is constitutively degraded through its phosphorylation by glycogen synthase kinase 3-β in a large protein complex brought together by axin and adenomatous polyposis coli.[57] Phosphorylated β-catenin is recognized by a β-transducin repeat containing protein (β-TrCP) that targets it for proteasome-mediated degradation. In the presence of Wnt stimulation, the Wnt ligands bind to two synergistically acting families of Wnt (co)receptors: the Frizzled receptor family members and low-density lipoprotein receptor-related proteins (LRP5 or LRP6). This interaction results in the recruitment of axin to LRP5/6 in the plasma membrane; this sequestering of axin at the plasma membrane may lead to disassembly of the β-catenin destruction complex or, alternatively, induce the association of the complex with phosphorylated LRP5/6, blocking ubiquitination of β-catenin by β-TrCP. In either model, the degradation of β-catenin is inhibited, and the protein is stabilized. Stabilized β-catenin protein then accumulates in the cytoplasm and translocates to the nucleus, where it interacts with members of the T cell factor/lymphoid enhancer factor family of DNA-binding transcription factors to regulate the expression of downstream target genes.[57]

During the past two decades, canonical Wnt signaling has been shown to play a significant role in the control of osteoblastogenesis and bone formation. Genetic studies analyzing conditional β-catenin loss- and gain-of-function mouse models provided compelling evidence that β-catenin is a crucial transcription factor determining the osteoblast lineage commitment of mesenchymal progenitors.[58] During development, β-catenin is indispensible for suppressing chondrocytic differentiation of bipotent osteochondroprogenitor cells and for stimulating them to differentiate into mature osteoblasts.[9] Inactivation of β-catenin in mesenchymal progenitor cells blocked osteoblast differentiation, and mesenchymal cells in the perichondrium and calvarium differentiated into chondrocytes instead. In postnatal life, deletion of the gene encoding β-catenin in Osx-expressing osteoprogenitors inhibited their differentiation into mature osteoblasts, and instead induced the expression of adipocytic markers.[59,60]

The roles of the canonical Wnt pathway in osteoblasts have been clarified largely through genetic studies in mice.[58] Combined deletion of the key Wnt coreceptors LRP5 and LRP6 in the embryonic mesenchyme largely recapitulated the loss of β-catenin, the phenotypes being characterized by impaired osteoblast differentiation in the developing mutant mouse skeletons. Similarly, LRP5-deficient mice developed a low bone mass phenotype postnatally owing to reduced osteoblast number and function, and additional deletion of one allele of *LRP6* led to a further reduction in bone mass.[58]

Clinically, mutations in the Wnt receptor complexes have been amply associated with changes in bone mineral density and fractures.[61] Loss-of-function mutations in LRP5 receptors cause osteoporosis-pseudoglioma syndrome, a form of juvenile-onset osteoporosis, in humans.[62] Conversely, gain-of-function mutations that render LRP5 refractory to secreted antagonists of canonical Wnt signaling such as Dickopff-related 1 (DKK1) and sclerostin (encoded by the *SOST* gene), result in high bone mass phenotypes.[63] These protein inhibitors of Wnt signaling have additional clinical relevance. For example, increased production of DKK1 appears to contribute to the bone loss in patients with multiple myeloma.[64] Moreover, homozygous loss-of-function mutations in SOST have been identified in patients diagnosed with sclerosteosis, a disfiguring disease associated with high bone mass. Mutations affecting regulation of SOST transcription cause van Buchem disease, a disease that resembles sclerosteosis.[61] These findings highlight the important role of canonical Wnt signaling in regulating human bone mass.

Runx2 and Osx. Runx2 (previously known as Cbfa1, OSF2, or AML3), a transcription factor of the ancient runt family, has been demonstrated to be absolutely essential for the induction of osteoblast differentiation and endochondral and intramembranous bone formation. RUNX2-deficient mice completely lack osteoblasts and do not form bone at all; instead, a completely cartilaginous skeleton develops without any true bone matrix.[65,66] In heterozygous (haploinsufficient) *RUNX2* mutant mice, the defect in osteoblast differentiation is limited to intramembranous bones.[65] The resulting phenotype in these mice closely resembles the cleidocranial dysplasia syndrome in humans, a dominantly inherited developmental disorder of bone, in which *RUNX2* was found to be mutated in most patients.[67,68]

Runx2 can be sufficient to induce osteoblast differentiation *in vitro*. Moreover, *RUNX2*-null calvarial cells spontaneously differentiate into adipocytes and differentiate into chondrocytes in the presence of BMP-2 *in vitro*, but they do not differentiate into osteoblasts. Thus, Runx2 is both sufficient and essential for differentiation of mesenchymal cells into osteoblasts, and it inhibits their differentiation into adipocytes and chondrocytes. Runx2 mediates osteoblast differentiation by regulating the expression of a variety of bone matrix protein genes, and by stimulating mineralization in immature mesenchymal cells and osteoblastic cells. The DNA-binding sites of Runx2 have been identified in major osteoblast-specific genes, including the genes that encode type I collagen (Col1a1), osteopontin, osteonectin, bone sialoprotein, osteocalcin, and Runx2 itself, and Runx2 induced the expression of these genes or activated their promoters *in vitro* (for review, see Komori[18]).

Runx2 also regulates the expression of Osx (encoded by the *OSX* or *SP7* gene), a specificity protein family transcription factor with three zinc-finger motifs. Osx is expressed in osteoblast progenitors, in osteoblasts, and at a lower level in (pre-)hypertrophic chondrocytes.[69] Similar to Runx2-deficient mice, mice lacking OSX showed complete lack of osteoblasts and absence of both intramembranous and endochondral bone formation.[69] Thus, Osx is a third transcription factor that is essential for osteoblast differentiation. Because Runx2 is expressed in the mesenchymal cells of OSX-null mice, but OSX is not expressed in RUNX2-null mice, it can be concluded that Osx acts downstream of Runx2.[69] Furthermore, the *OSX* gene contains a consensus Runx2-binding site in its promoter region, suggesting that it might be a direct target of Runx2. The transcriptional activity of Osx involves its interaction with NFATc1, cooperatively forming a complex that binds to DNA and induces the expression of *COL1A1*. Overall, it is currently thought that Runx2 has a crucial role in the earliest determination stage of the osteoblast lineage, driving mesenchymal progenitors to become preosteoblasts, whereas Osx regulates at a later stage the differentiation of preosteoblasts to functional, bone-forming osteoblasts expressing high levels of osteoblast markers (see Fig. 51.6).[18]

Other Factors and Signaling Molecules Involved in Osteoblastogenesis. Signaling pathways involving BMPs, Ihh, and FGFs have been mentioned previously in this chapter for their roles in chondrogenesis, but these signals also exert important functions in osteoblastogenesis and bone formation. Although several BMPs are extremely powerful in inducing bone formation when administered exogenously, their biological functions in osteoblast differentiation and endochondral ossification are less clear. Among BMP family members, BMP-2, BMP-4, and BMP-7 have been studied most extensively for their roles in osteogenesis during development, postnatal bone formation and remodeling, and fracture repair (reviewed in Lowery & Rosen[14] and Salazar et al.[70]). Double knockout of BMP-2 and BMP-4 in the limb completely disrupted osteoblast differentiation, demonstrating the crucial roles of these two BMPs in osteoblast differentiation. Effects of BMP signaling in later stages of osteoblast differentiation are suggested by studies using BMP antagonists. Targeting of Noggin overexpression to differentiated osteoblasts by use of the osteocalcin promoter in an animal model results in osteopenia by 8 months of age. Likewise, overexpression of Gremlin, another BMP antagonist, in differentiated osteoblasts in mice results in reduced bone mineral density and fractures. Moreover, deletion of *SMAD4*, which encodes a downstream effector of BMP signaling, in mature osteoblasts led to reduced osteoblast function. BMP-2 in particular plays important roles in osteogenic differentiation, postnatal bone formation, and fracture healing; the activity of BMP-2 as a potent inducer of bone formation is being applied as a therapeutic strategy to repair bone defects in humans.[14,70] Regarding the receptors, it is known that activating mutations in the BMP type I receptor ALK2 cause fibrodysplasia ossificans progressive, a human disease characterized by ectopic bone formation that recapitulates the entire sequence of endochondral ossification.[71] Still, much remains to be learned about the physiologically relevant BMP receptors in osteoblasts.

The Hedgehog family member Ihh is required for endochondral, but not intramembranous, bone formation in the skull, by controlling osteoblast differentiation in the perichondrium of long bones. IHH-null mice completely lack endochondral ossification because of the lack of osteoblasts.[17,72] In these mice, RUNX2 expression and nuclear β-catenin are absent in the perichondrium. Thus, Ihh is required for inducing the initial activity of Runx2 and β-catenin in perichondrial cells and triggering them to become endochondral osteoblasts, thereby coupling chondrocyte maturation with osteoblast differentiation during endochondral ossification (reviewed in Maes[21]). The role for Hedgehog signaling in osteoblast-lineage cells proper during adult bone homeostasis is less clear.

FGF signaling has been implicated in the proliferation of immature osteoblasts and the anabolic function of mature osteoblasts *in vivo*, in both the fetal and postnatal stages.[12] In mice lacking FGF18, osteoblast progenitors could be identified in the bone collar, but their terminal differentiation was delayed resulting in delayed ossification. Mice lacking FGF2 showed a reduction in total bone mass at the adult stage, which was probably owing to reduced osteoprogenitor proliferation and decreased osteoblast function.[12] Several FGF receptors (FGFR1, FGFR2, and FGFR3) have been implicated in the osteogenic functions of FGF signaling, as revealed by genetic studies in mice, although FGF signaling through different receptors appears to have diverse roles in regulating osteoprogenitor proliferation, osteoblast differentiation, and the activity of mature osteoblasts.[12]

KEY POINTS

- The formation of osteoblasts and their descendants (bone lining cells and osteocytes) requires the actions of transcription factors, most crucially Runx2, Osterix (Osx), and β-catenin/T cell factors/lymphoid enhancer factor. The expression of these and other transcription factors are regulated by locally produced Indian hedgehog (Ihh), Wnts, bone morphogenetic proteins (BMPs), fibroblast growth factors (FGFs), and other paracrine factors, which in turn are also regulated by inhibitors of these pathways.

Osteoclastogenesis and Skeletal Tissue Resorption

At the time of vascular invasion of hypertrophic cartilage, the chondrocytes are generally thought to mostly die through apoptosis, and remaining cellular debris and matrix components become degraded and are digested by coinvading osteoclasts (or related cells termed chondroclasts that have been postulated in the context of resorption of cartilage[30]) and endothelial cells through their proteolytic enzyme products.[30,73] Beyond development, the osteoclast remains a key participant in the regulation of bone mass, as bone is constantly being remodeled throughout life (see before and Fig. 51.3). Several pathologic conditions are because of an imbalance between bone formation and resorption, most frequently involving excessive osteoclast activity (see later). Such skeletal diseases include osteoporosis, a common low bone mass disorder typically prevalent in postmenopausal women, as well as periodontal disease, rheumatoid arthritis, multiple myeloma, and metastatic cancer. On the other hand, osteopetrosis, a rare human disease characterized by increased bone mass and obliteration of the bone marrow cavity, is caused by impaired osteoclast differentiation and/or function. Many efforts have been made to dissect the regulatory pathways leading to functional osteoclasts (Fig. 51.7).[74,75]

Osteoclastogenesis. Osteoclasts are giant multinucleated cells that have the unique capacity to efficiently degrade mineralized tissues. Osteoclasts are derived from hematopoietic precursor cells of the myelomonocytic lineage and share a common precursor with macrophages. Recognition of the intertwining control and close interactions of the immune and skeletal systems has led to the emergence of the integrating field of osteoimmunology.[76,77] Early differentiation of the bipotential macrophage/osteoclast precursor cells is regulated by PU.1, a versatile hematopoietic cell-specific transcriptional regulator belonging to the ETS family of transcription factors. The commitment to macrophages/osteoclasts is dependent on a high level of activity of PU.1 (Fig. 51.7); PU.1 regulates the lineage fate decision of early progenitors by directly controlling expression of the *C-FMS* gene, which is a key determinant of differentiation into the macrophage/osteoclast lineage; PU.1-null mice lack both macrophages and osteoclasts and are osteopetrotic. PU.1 also regulates the transcription of another key osteoclastogenesis control gene, encoding receptor activator of nuclear factor-κB (*RANK*), in myeloid progenitors. Although mature macrophages and osteoclasts have some cell surface markers in common, the latter express high levels of tartrate-resistant acid phosphatase (TRAP), cathepsin K, vitronectin, calcitonin receptor, and $\alpha_v\beta_3$ integrin, which typify the osteoclast lineage (also see later).[74,75]

After the precursor cells have committed to the osteoclast lineage, they are subjected to a complex multistep process that culminates in the generation of mature, multinuclear, activated osteoclasts; these steps include proliferation, maturation, and fusion of differentiating precursor cells, and finally activation of resorption (see Fig. 51.7). Two critical cytokines are essential for osteoclastogenesis: macrophage-colony stimulating factor (M-CSF) and RANK ligand (RANKL).[74-77] Both these signaling molecules are expressed by bone marrow stromal cells (i.e., osteoblast progenitors) and osteoblasts; M-CSF is produced in both a soluble and a membrane-bound form, and RANKL is made as a membrane protein by osteoblasts. Both PTH and $1,25(OH)_2D_3$, as well as several other osteotropic factors stimulating resorption, increase the expression of RANKL on stromal/osteoblastic cells (see later). RANKL, together with M-CSF, is sufficient to induce *in vitro* osteoclast differentiation from spleen- or bone marrow–derived precursors in the complete absence of stromal/osteoblastic cells.

Osteocytes have also been recognized as a major source of RANKL driving osteoclast formation and activation during adult bone remodeling in mice,[78,79] and may thus be crucial regulators of osteoclast formation (Fig. 51.7). Furthermore, not only osteoblast lineage cells but also chondrocytes and T cells synthesize and secrete RANKL and are able to support osteoclastogenesis. Production of RANKL by

Fig. 51.7 Osteoclastogenesis. The transcription factor PU.1 is indispensable for development of the osteoclast and macrophage (*Mφ*) lineages from a common myeloid precursor. Macrophage-colony stimulating factor (*M-CSF*) acting upon the receptor c-Fms is required for the conversion of the progenitor to a preosteoclast. Signaling through the membrane-bound receptor activator of nuclear factor-κB (*RANK*) promotes further differentiation of preosteoclasts to mature polykaryotic osteoclasts and their subsequent activation to bone-resorbing cells that secrete protons and lytic enzymes. RANK signaling is induced by receptor activator of nuclear factor-κB ligand (*RANKL*), present on bone marrow stromal cells, osteoblasts, and osteocytes, as well as on lymphocytes and possibly in a soluble form in serum. The soluble antagonist osteoprotegerin (*OPG*) competes with RANK for RANKL binding, thereby functioning as a negative regulator of osteoclast differentiation, activation, and survival. RANKL expression is induced by proresorptive and calciotropic factors that stimulate osteoclastogenesis. Conversely, OPG is induced by factors that block bone catabolism and promote anabolic effects. *PTH,* parathyroid hormone; *PTHrP,* parathyroid hormone-related peptide; *IL,* interleukin; *TNF,* tumor necrosis factor; *BMPs,* bone morphogenetic proteins; *PDGF,* platelet-derived growth factor.

hypertrophic chondrocytes may be important physiologically for osteoclast differentiation and invasion of the hypertrophic cartilage during endochondral bone development and growth, and RANKL produced by T cells definitely plays a major role pathologically in numerous inflammatory conditions affecting the skeleton, including rheumatoid arthritis, periodontitis, and osteomyelitis, in which immune cells are activated in bones and joints. For instance, production of RANKL by T cells has been implicated as an activator of osteoclastic resorption in inflammation-mediated bone and cartilage destruction in rheumatoid arthritis, in which it likely works synergistically with tumor necrosis factor (TNF)-α and interleukin (IL)-17.[74-77]

M-CSF and RANKL affect several steps of the osteoclastogenesis cascade by binding to their respective receptors, C-FMS and RANK, which are expressed by osteoclast progenitors and osteoclasts at all stages of differentiation. M-CSF signaling is essential early on in the lineage for proliferation, differentiation, and survival of osteoclast/macrophage precursors. The essential roles of M-CSF were illustrated through analysis of mice carrying the *op/op* mutation, an inactivating point mutation in the *M-CSF* gene; these mice have osteopetrosis with low numbers of macrophages and a complete lack of mature osteoclasts.[74-77]

RANKL is an essential inducer of multiple aspects of osteoclastogenesis, including osteoclast differentiation, fusion, activation of mature osteoclasts to resorb mineralized bone, and survival.[74-77] Through these actions, RANKL potently stimulates bone resorption. RANKL acts by binding to its signal transducing receptor, RANK, a member of the TNF receptor family present on preosteoclasts and mature osteoclasts. Consistent with this, an activating mutation of the human *RANK* gene was found in patients with familial expansile osteolysis, a disease of excess bone resorption. Following the discovery of the RANK/RANKL system, numerous genetic and cell biological studies have been performed to elucidate the complex signaling cascade downstream of RANK/RANKL. Briefly stated and oversimplified, the binding of RANKL to RANK on the surface of osteoclast precursors recruits the adaptor protein/ubiquitin E3 ligase, TNF receptor-associated factor 6, to the cytoplasmic domain of RANK, leading to activation of NF-kB and its translocation to the nucleus. NF-kB increases C-FOS expression, and C-FOS, as a component of the activator protein complex, interacts with the master transcription factor for osteoclastogenesis, nuclear factor of activated T cells c1 (NFATc1), to induce osteoclast-specific genes (such as the genes encoding TRAP and calcitonin receptor). Costimulatory molecules act in concert with RANK to activate phospholipase C, thereby increasing intracellular calcium and activating NFATc1.[74]

The actions of RANKL are regulated negatively by a secreted soluble decoy receptor termed osteoprotegerin (OPG), also a member of the TNF receptor superfamily. OPG sequesters RANKL molecules, thereby blocking their binding to RANK. As such, OPG protects bone from excessive resorption. Correspondingly, certain homozygous deletions of *OPG* in humans can cause juvenile Paget disease, a disorder characterized by increased bone remodeling, osteopenia, and fractures. The relative concentrations of RANKL and OPG in bone thus are major determinants of bone mass and strength.[74-77]

Other regulatory molecules have been implicated in the late stages of osteoclast differentiation, the fusion process, and activation of resorption. The fusion of mononuclear osteoclast precursor cells into mature multinucleated osteoclasts is regulated by a membrane protein called dendritic cell-specific transmembrane protein (DC-STAMP). DC-STAMP–deficient cells failed to fuse, and these mononuclear osteoclasts had reduced resorptive efficiency in vitro. Consequently, DC-STAMP–deficient mice exhibited increased bone mass. These data suggest that multinucleation and osteoclast enlargement could be associated with a higher degree of resorption efficiency.[74-77] Pathologically huge osteoclasts containing substantially more nuclei than normal osteoclasts do are seen, for instance, in Paget disease of bone (up to 100 nuclei per cell; normal range is 3–20 nuclei per cell), in which localized excessive bone remodeling is initiated by increases in osteoclast-mediated bone resorption.[80]

In summary, RANKL and OPG act in an antagonistic fashion to regulate bone resorption, and their respective expression levels are under the control of proresorptive and antiresorptive factors, including several hormones, cytokines, and growth factors (see Fig. 51.7, top). The discovery of the RANK/RANKL/OPG signaling pathway has led to the development of drugs (e.g., denosumab, an anti-RANKL antibody) to suppress excessive osteoclast formation for clinical use in a variety of bone diseases, including osteoporosis, autoimmune arthritis, periodontitis, Paget disease, and bone tumors/metastases.[74,77]

Bone Resorption: Osteoclast Action and Proteolytic Enzymes.

Bone resorption involves both dissolution of bone mineral and degradation of organic bone matrix. Osteoclasts are highly specialized to perform both of these functions. Upon activation of mature multinucleated osteoclasts, the cells attach themselves firmly to the bone surface, using specialized actin-rich podosomes (actin ring), through cytoskeleton reorganization and cellular polarization.[81] Within these tightly sealed zones of adhesion to the mineralized matrix, the osteoclasts form convoluted, villus-like membranes called “ruffled borders,” which substantially increase the surface area of the cell membrane facing the resorption lacuna (Howship’s lacuna). Via these ruffled membranes, the osteoclasts secrete abundant hydrochloric acid (involving the vacuolar H^+-ATPase proton pump), mediating acidification of the compartment between the cell and the bone surface, as well as a myriad of enzymes such as lysosomal cathepsins, the phosphatase TRAP, and proteolytic MMPs (see later). The acidity of the environment leads to dissolution of the mineral phase (crystalline hydroxyapatite), activation of lytic enzymes, and digestion of organic matrix compounds (see Fig. 51.8). The sealing mechanism allows localized dissolving and degrading of the mineralized bone matrix, while simultaneously protecting neighboring cells from harm.[82] During the resorption process, dissolution of hydroxyapatite releases large amounts of soluble calcium, phosphate, and bicarbonate. Removal of these ions is needed (e.g., to maintain the acidic pH in the resorption lacuna) and involves vesicular pathways and direct ion transport via different ion exchangers, channels, and pumps. The degradation products of the organic matrix after enzymatic digestion are transcytosed through the cell for secretion at the basolateral membrane.[82]

These complex processes of osteoclast recruitment, polarization on the bone surface, and export of acid and enzymes are orchestrated by many factors, including RANKL, as well as by integrin-mediated signaling from the bone matrix itself.[81] The latter, which is particularly represented by the αvβ3 integrin in osteoclasts, was suggested to be important for osteoclast functioning based on the finding that inhibition of signaling through this αvβ3 integrin inhibited osteoclast-mediated bone resorption *in vitro* and in animal models of osteoporosis and malignant osteolysis. Integrins are heterodimeric cell-surface receptors, composed of an α and a β subunit, that mediate cell-matrix interactions and thus adhesion. The αvβ3 integrin, which is the most highly expressed integrin in osteoclasts, recognizes Arg-Gly-Asp-containing matrix proteins such as vitronectin, osteopontin, and bone sialoprotein. Several components of the αvβ3 integrin signaling pathway localize to the sealing zone of actively resorbing osteoclasts and play a role in linking the matrix adhesion of osteoclasts to cytoskeletal organization, cell polarization, and activation for bone resorption. Upon its activation, αvβ3 integrin stimulates an intracellular signaling complex involving the tyrosine kinases C-SRC and SYK. The importance of αvβ3, C-SRC and SYK in osteoclast activity is underscored by the development of osteopetrosis in mice deficient in each of these genes, because of lack of bone resorption.[81,82]

Many of the molecules that are important for osteoclast function *in vitro*, such as β3 integrin, C-SRC, cathepsin K, carbonic anhydrase II, TRAP, and several ion channel proteins, cause an osteopetrotic phenotype when deleted in mice or altered in humans. The absence of these genes does not affect the differentiation into morphologically normal osteoclasts; however, the osteoclasts are not functional, and they fail to resorb bone effectively.[83] For instance, cathepsin K, which is the key enzyme in the digestion of bone matrix owing to its activity in degrading type I collagen, is highly expressed by activated osteoclasts and secreted in the resorption lacuna. Its deletion in mice led to osteopetrosis, and mutations in the human cathepsin K gene cause pycnodysostosis. Highly selective and potent cathepsin K inhibitors have been developed and tested in clinical trials to assess their usefulness as antiresorptive agents for the treatment of osteoporosis and to reduce breast cancer-induced osteolysis and skeletal tumor burden, but adverse side effects and roles of cathepsin K beyond bone complicate the drug development.

Besides cathepsin K, several proteolytic enzyme groups are involved in the degradation of organic components (collagens and proteoglycans) of bone and cartilage matrices after the mineral is dissolved. One of these is the MMP family, which contains over 25 members, including secreted collagenases, stromelysins, gelatinases, and membrane-type (MT)-MMPs. Several MMPs, including MMP9 and MMP14 (also known as MT1-MMP), are highly expressed in osteoclasts/chondroclasts, but they are produced by many other cell types as well. Both of these molecules play a role in the cartilage resorption process associated with invasion by blood vessels and osteoclasts during endochondral ossification.[30,73,84]

KEY POINTS

- Osteoclasts are multinucleated cells with a hematopoietic origin shared by macrophages. They play crucial roles in resorbing both the mineral phase and matrix of bone by secreting acid and multiple proteolytic enzymes during development and bone remodeling. A complex series of receptors and transcription factors guide the differentiation of osteoclasts in response to macrophage-colony stimulating factor (M-CSF) and receptor activator of nuclear factor-κB ligand (RANKL), which are made by multiple cell subsets of the osteoblast lineage. In this way, the osteoblast lineage controls the activities of osteoclasts and the sites at which they act.

REGULATION OF BONE REMODELING AND BONE MASS

Coupling of Bone Resorption and Bone Formation During Remodeling

Skeletal homeostasis remains intact as long as the activities of both osteoclasts and osteoblasts are balanced (coupled), and the net bone mass is maintained (also see Fig. 51.3). This balance implies the existence of mechanisms that tightly coordinate the differentiation of osteoblasts and osteoclasts, as well as their migration to locations where they function. Increasing data support the model that osteoclasts and osteoblasts reciprocally regulate each other's recruitment, differentiation, and/or activity. In addition, osteocytes increasingly emerged as key players in the remodeling process by regulating both osteoclastic bone resorption and osteoblastic bone formation.

A first aspect of the coupling principle is provided by the direct control of osteoclastogenesis by cells of the osteoblast lineage. Indeed, as outlined above, osteoblasts and stromal cells control bone degradation by expressing M-CSF, required for the proliferation of osteoclast precursors, and RANKL, mediating the differentiation of hematopoietic osteoclast precursors toward mature multinucleated osteoclasts. Osteoblasts also express OPG, the soluble decoy receptor that binds to RANKL and prevents it from binding to RANK, thus providing a negative control mechanism to limit osteoclastogenesis (see Fig. 51.7).[74-76] Osteocytes, as sources of RANKL, are additional players in the regulation of osteoclast formation and activation during bone remodeling.[78,79]

Other mechanisms by which osteoblast lineage cells control osteoclastogenesis *in vivo* are being increasingly uncovered through the use of cell type and/or stage-specific mutagenesis in mice (for recent reviews, see Sims & Martin[85]and Kim et al.[86]). For instance, the noncanonical Wnt pathway (Wnt signaling relayed to intracellular responses by mechanisms that are independent of β-catenin actions) between osteoblast-lineage cells and osteoclast precursors appears to regulate bone resorption.[87] Another newly identified mechanism involves osteoblastic expression of semaphorin 3A (SEMA3A), a member of the family of secreted and membrane-associated axon guidance molecules that use plexins and neuropilins (NRPs) as their primary receptors; soluble SEMA3A produced by osteoblasts was found to exert an osteoprotective effect by inhibiting osteoclast precursor differentiation through the Plexin-A coreceptor NRP1.[88] In contrast, SEMA6D signaling through the receptor Plexin-A on osteoclasts was found to promote osteoclast formation and function.[89] Hence, this system's complexity, with multiple interacting ligands and receptors, calls for further studies to clarify their precise roles in osteoblast-osteoclast communication (also see following).

The second, converse aspect of the coupling is provided by the reciprocal activity of osteoclasts to modulate osteoblast recruitment, differentiation, and function to regulate the anabolic arm of the remodeling process that follows the resorption phase (see Fig. 51.3). In the coupling of osteoclasts to cells of the osteoblast lineage, three types of osteoblastogenic signals can be discriminated: (1) bone resorption–derived signals, most typically comprising growth factors that were embedded in bone matrix and become released upon osteoclastic bone resorption (e.g., TGFβ, BMPs, IGFs, PDGF); (2) osteoclast-derived and other soluble signals (e.g., hormones and diffusible growth factors, such as BMP-6, S1P, and Wnt10b); and (3) cell-surface interactions between osteoclasts and developing osteoblasts, mediated by membrane-bound molecules (e.g., ephrins, semaphorins).[85,86,90] These three classes of coupling mediators are discussed next.

Osteoclastic bone resorption is generally assumed to locally release a myriad of growth factors that are stored in the bone matrix, which can subsequently act as potent osteoblast stimuli by attracting osteoblastic cells or their progenitors to the remodeling site and/or stimulating their proliferation, differentiation and activity.[28] Growth factors like TGFβ, BMPs, IGFs, VEGF, and PDGF produced by osteoblasts are incorporated into the bone matrix in high concentrations; when released, they can elicit their anabolic effects on osteoblast lineage cells. One key aspect about which many questions remain is how osteoblast progenitors are initially recruited to the remodeling site. Constituents of the bone matrix, such as fragments of collagen or osteocalcin, complement fragments, inflammatory cytokines, and growth factors that are typically released, activated, or produced at sites of matrix resorption have all been reported to exert chemotactic potential toward osteoblasts and their precursors *in vitro* (reviewed Dirckx et al.[28]). For instance, release of TGFβ from the bone matrix during osteoclastic bone matrix degeneration was reported to exert a chemotactic effect on osteoblast precursors to these bone resorptive sites.[91] Similarly, IGF-1 released from the bone matrix upon resorption was found to promote osteoblastic differentiation of recruited SSCs by activation of mammalian target of rapamycin, thereby maintaining proper bone mass.[92]

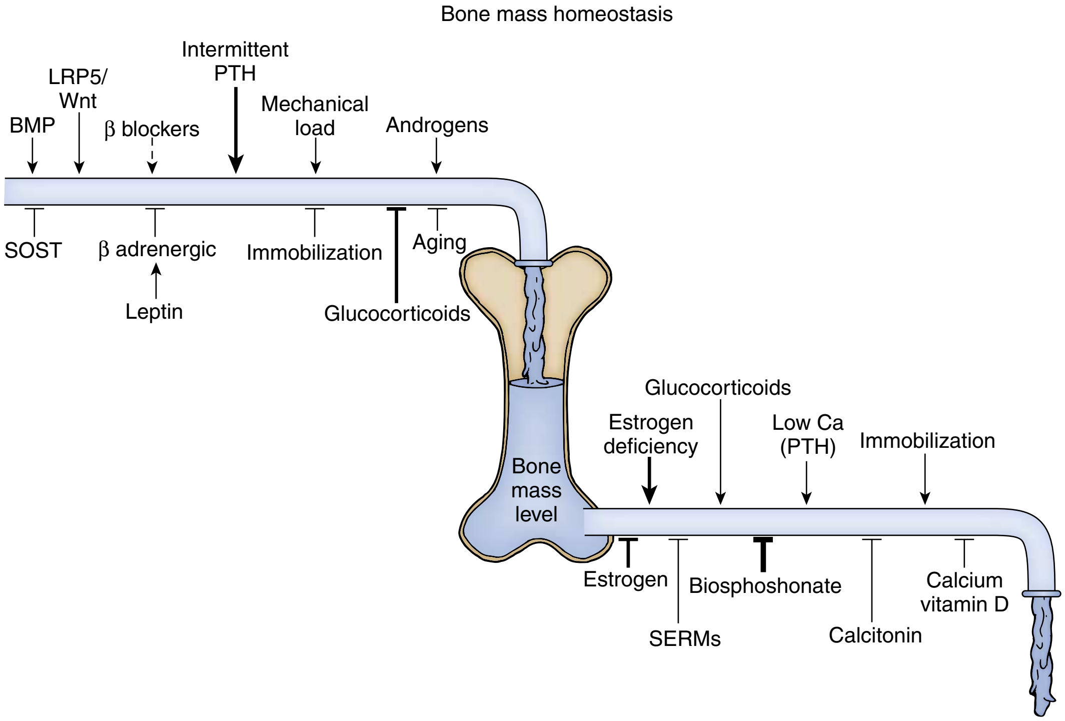

Fig. 51.8 **Control of Skeletal Homeostasis and Bone Mass.** Schematic representation of the "servo" system that maintains bone mass at steady-state levels. Physiologic and pharmacologic stimulators and inhibitors of bone formation and resorption are listed. The relative impact, where known, is represented by the thickness of the arrows. *SERM*, Selective estrogen receptor modulator; *BMP,* bone morphogenetic protein; *SOST,* sclerostin; *PTH,* parathyroid hormone; *LRP,* lipoprotein receptor–related protein; *Ca,* calcium, (Modified from Harada S, Rodan GA. Control of osteoblast function and regulation of bone mass. *Nature*. 2003;423:349–355.)

In addition to chemotactic signals released from the matrix upon resorption, osteoclasts can also play a direct role in regulating osteoblast recruitment. For instance, osteoclasts themselves secrete factors with chemotactic properties, such as PDGF, that can stimulate osteogenesis and angiogenesis in parallel.[28] Other molecules with anabolic potential that are expressed by osteoclasts include BMP-6, S1P, the Wnt agonist Wnt10b, and the adiponectin family member collagen triple helix repeat containing 1 (CTHRC).[85,86,90] When CTHRC was deleted only from osteoclasts in mice, osteopenia resulted; thus, this protein is likely to have a physiological role in the coupling mechanism.[93] Of note, osteocytes also play a role in determining osteoblastic differentiation and bone formation during remodeling by modulating Wnt signaling, for instance through their expression of the Wnt inhibitors DKK1 and sclerostin.

Lastly, osteoclasts can also signal directly to cells of the osteoblast lineage through cell-bound molecules.[85,86,90] For instance, the ephrin/Eph receptor system may allow bidirectional cell-surface contact based signaling between osteoclasts and osteoblasts. It was reported that osteoclasts express ephrin B2, whereas osteoblasts express its EphB4 receptor, both membrane-bound proteins. Signaling through EphB4 into osteoblasts (forward signaling) appeared to enhance osteogenic differentiation, whereas signaling through ephrin B2 into osteoclast precursors (reverse signaling) suppressed osteoclast differentiation, the overall outcome of such interaction thus being predicted to favor bone formation. Other studies have argued that ephrin B2 is produced by the osteoblast lineage, thus contesting the view of an osteoclast-derived coupling activity.[90] Another study showed that osteoclast-produced SEMA4D, a predominantly transmembrane semaphorin, contributes to balanced remodeling in adult bone by binding to its receptor Plexin-B1, expressed on osteoblasts. Altogether, although many details remain to be uncovered, it is clear that osteoclasts are capable of producing many molecules affecting the osteoblast lineage, both positively and negatively.[85,86,90]

KEY POINTS

- Osteoblasts and osteoclasts use multiple mechanisms to communicate with each other. Local factors produced by cells of the osteoblast lineage, such as semaphorins and noncanonical Wnts, complement macrophage-colony stimulating factor (M-CSF) and receptor activator of nuclear factor-κB ligand (RANKL) to regulate osteoclastogenesis and the activities of mature osteoclasts. Osteoclasts use several distinct types of mechanisms to influence osteoblastic cells. Osteoclastic bone resorption leads to release of cytokines and growth factors from the bone matrix that can attract osteoblast precursors and accelerate their differentiation and activities. Osteoclasts themselves also secrete factors that act on osteoblast lineage cells, and they express cell surface proteins that signal directly to osteoblast lineage cells through cell–cell contact.

Local, Systemic, and Central Regulators of Bone Remodeling

Bone remodeling and the resultant net bone mass are influenced by a myriad of signals (Fig. 51.8). In addition to the many local factors that were discussed previously, bone resorption and bone formation are also profoundly affected by mechanical stimuli, endocrine molecules, and central regulatory systems, that consequently impact strongly on the balance between the two processes, and hence on bone health.

Mechanical Loading. The skeletal system provides mechanical support and protection for the multiple organs of vertebrate organisms. To withstand loading in the most efficient way (maximal strength for minimal material), the skeleton constantly adjusts its bone mass and architecture in response to load through bone remodeling. In fact, adaptation and reshaping of the bone structure to mechanical forces require the replacement of existing bone packets or whole trabeculae with new ones appropriately oriented relative to prevailing mechanical loads. The close, dynamic relation between bone structure and the lines of force in bone may be maintained by responses to a mechanical strain threshold (force per unit area), below which osteoclastic removal of bone occurs, while a higher strain will stimulate the addition of bone. It has indeed long been recognized that mechanical stress induced by weight-bearing exercise increases osteoblast activity and induces bone formation. Conversely, the absence of mechanical stimulation resulting from prolonged immobilization or unloading causes severe bone loss. During immobilization, bone resorption increases and formation decreases, contributing to the bone loss seen to be associated with frailty and prolonged bed rest. Similarly, prolonged space flight, with the resulting lack of gravity forces on the skeleton, leads to marked loss of bone mass and increased bone fragility in astronauts.

Increasing evidence suggests that the main mechanosensing cell type of bone is the osteocyte (see earlier). The osteocyte is ideally situated within the lamellar bone to sense mechanical forces and communicates signals to other osteocytes, osteoblast lineage cells, and osteoclasts on the bone surface, likely through the connecting canalicular network.[54-56] Osteocytes also respond to increased load by altering their signaling, resulting in the translation of mechanical stimuli into biochemical signals that generally enhance osteoblastic bone formation and reduce osteoclastic bone resorption. For instance, osteocytes take part in the control of bone formation through the production of sclerostin, the protein derivative of the *SOST* gene that inhibits Wnt signaling through binding to LRP5/6 (see earlier); mechanical loading results in a rapid decrease in the *SOST* expression levels in osteocytes, suggesting that osteocytes transmit signals of mechanical loading to osteoblast lineage cells on the bone surface by modulating the Wnt/β-catenin pathway.[54-56] As also discussed earlier, osteocytes have the potential to stimulate bone resorption by producing RANKL, and the levels of RANKL versus OPG could be regulated by mechanical stimulation. Mechanical stimulation is also capable of maintaining osteocyte viability, which seems important in the response to mechanical signals. Experimental destruction of osteocytes in a genetic mouse model conferred resistance to unloading-induced bone loss.[94] The precise mechanisms by which a mechanical stimulus is transduced into biochemical signals in osteocytes and osteoblasts and the means whereby these cells then modulate bone remodeling activities have not been clearly identified yet.[54-56]

Parathyroid Hormone. Bone remodeling also represents a major mechanism used by land vertebrates to regulate mineral homeostasis. The removal of calcium from bone, to maintain calcium homeostasis acutely, is facilitated by osteoclastic resorption of calcium-containing bone. The principal mediators in this process are PTH and its downstream effector $1,25(OH)_2D_3$, the activities of which are discussed in detail in other chapters in this book. Both these hormones act on osteoblastic cells to increase the production of RANKL and thereby potently activate osteoclastogenesis.[95]

The actions of PTH on bone are complex, with multiple direct actions on cells of the osteoblast lineage that vary both with the state of differentiation of the cell and with its location in bone (periosteal vs. endosteal). The actions of PTH to increase osteoclast number and action dominate when levels of PTH are continuously elevated, but PTH also increases the rate of bone formation. In fact, when PTH is administered intermittently, this effect predominates and leads to a net increase in bone mass (see Fig. 51.8).[96] PTH action directly on osteocytes may be involved in the control of both bone resorption and bone formation. PTH and, during lactation, PTHrP can also stimulate osteocytes to directly dissolve bone matrix and release calcium into the bloodstream (osteocytic osteolysis).[54,55,97] How much osteoclastic osteolysis and osteocytic osteolysis each contribute to release of mineral from bone is an area of active investigation.

When administered intermittently, PTH enhances RUNX2 expression and activity; however, RUNX2 is also involved in the catabolic effect of PTH through the induction of RANKL.[95,98] Intermittent PTH promotes osteoblast differentiation also in part by its ability to promote exit from the cell cycle, to activate Wnt signaling in osteoblasts, and to inhibit production of the Wnt antagonist sclerostin in osteocytes. Furthermore, intermittent administration of PTH prolongs osteoblast survival, and increases osteoblast number by converting inactive lining cells to mature osteoblasts *in vivo*.[45] By controlling osteoblast function, PTH increases bone formation on cancellous, endocortical, and periosteal bone surfaces and has become a valuable clinical anabolic treatment strategy for osteoporotic conditions.[95,98]

Sex Steroids. Another significant endocrine input into bone remodeling and homeostasis is the pronounced influence of sex steroids, essential for maintenance of the adult skeleton (see Fig. 51.8; reviewed in Khosla et al.[99] and Manolagas et al.[100]) Skeletal preservation by estrogen in females may be related evolutionarily to the need for calcium stores for embryonic skeletal development. In mammalian adult males and females, including humans, estrogen has been identified as the major inhibitor of bone resorption that functions by reducing osteoclast number. This explains the profound bone loss associated with estrogen deficiency, with postmenopausal osteoporosis being the most prominent type of bone pathology in humans.

Estrogen actions on osteoclasts, which express estrogen receptors (ERα and ERβ), involve direct effects on their lifespan, through estrogen-mediated induction of the Fas/FasL system, causing apoptosis.[101] Furthermore, estrogen can have nongenomic effects, or rapid signaling effects, thus inducing the phosphorylation of components of various signaling pathways (e.g., the MAPK pathway) or calcium regulation. Such effects may contribute to the induction of osteoclast apoptosis by estrogen without the need for direct binding of ERα to DNA.[102] Besides affecting osteoclast lifespan, estrogen was reported to decrease the responsiveness of osteoclast progenitor cells to RANKL, thereby reducing osteoclastogenesis.[99,100]

Androgens are important not only as a source of estrogen, through the action of aromatase, but also for their direct effect in stimulating bone formation.[103] Testosterone, responsible for the male phenotype characterized by a larger skeleton, has complex effects on bone metabolism. As an anabolic steroid, it stimulates bone formation in both males and females. Androgens also increase periosteal bone formation, leading to larger and therefore stronger bones. Mice lacking the androgen receptor in osteoblasts and/or osteocytes displayed a phenotype characterized by reduced trabecular bone volume and accelerated age-related bone loss.[103] In addition, it is thought that testosterone can inhibit bone resorption directly, acting through the androgen receptor and through conversion by aromatase to estrogens.[103]

Other Systemic and Central Regulators of Bone Remodeling. In contrast to sex steroids, glucocorticoid excess is catabolic to bone, as is illustrated by glucocorticoid-induced osteoporosis, a devastating consequence of long-term use of glucocorticoids.[104] The mechanisms for glucocorticoid-induced bone loss are complex, including suppression of renal calcium reabsorption, reduction in intestinal calcium absorption, and hypogonadism, all of which lead to increased bone resorption and bone turnover. Perhaps more importantly, glucocorticoids have direct effects on the skeleton. Glucocorticoids impair the replication, differentiation, and function of osteoblasts and induce the apoptosis of mature osteoblasts and osteocytes, leading to dramatic suppression of bone formation. As well, glucocorticoids act directly on osteoclasts and prolong their lifespan; in addition, glucocorticoids may sensitize bone cells to regulators of bone remodeling and favor osteoclastogenesis, thus leading to overall increased bone resorption.[104] Influences on bone remodeling by the GH/IGF axis, thyroid hormones, and prostaglandins are reviewed in other chapters.

Signals from the central nervous system (CNS) and the sympathetic nervous system (SNS) also profoundly influence bone remodeling and resultant bone mass.[105,106] Leptin, an adipocyte-derived hormone mainly known for controlling appetite, energy metabolism, and reproduction, has been shown to act through the CNS (via the hypothalamus) and ultimately through the SNS to negatively regulate bone formation by osteoblasts. Sympathetic signaling via β_2-adrenergic receptors in osteoblasts inhibits proliferation through transcriptional factors such as Period, which also regulate the circadian clock, and additionally favors bone resorption by increasing osteoblastic expression of RANKL. These conclusions were drawn from a series of studies using mutant mice with deficiencies or lesions in portions of the leptin-hypothalamic-sympathetic pathways.[105] Furthermore, other neuroendocrine connections to bone remodeling have been made with the findings in mouse genetic and pharmacologic studies that both thyroid-stimulating hormone (TSH) and follicle-stimulating hormone (FSH) act directly on bone cells to influence remodeling.

Besides the mechanism of action of leptin through a central pathway, leptin appears to also act via peripheral pathways on osteoblasts to regulate bone mass and strength. The leptin receptor is present in bone marrow–resident stromal cells representing osteolineage progenitors (see earlier),[107] and the actions of leptin may be partly explained by direct effects on these cells.

Interestingly, whereas leptin represents an adipocyte-derived hormone regulating bone remodeling, through downstream effectors in bone that seem to be largely independent of its functions in energy metabolism and reproduction, a reciprocal regulatory function on energy metabolism and adiposity is exerted by osteoblasts. For instance, osteocalcin, one of the few osteoblast-specific gene products, is thought to act as a bone-derived signal modulating energy metabolism and adiposity. In its undercarboxylated form, which has a reduced affinity for the bone mineral, osteocalcin is released into the circulation and has been reported to function as an active hormone to increase pancreatic β cell proliferation, insulin expression and secretion, and insulin-sensitive glucose utilization and energy expenditure, and to reduce visceral fat.[108] In addition, recent studies using knockout mice indicated roles for osteocalcin in the regulation of brain development and adult brain function (including learning, memory, and emotional states), muscle mass, testosterone synthesis, and male fertility, as well as the acute response to stress, indicating that the endocrine actions of bone-derived osteocalcin are not limited to regulating energy metabolism.[109,110] On the other hand, recent studies of independently generated knockout rats and mice did not confirm the changes in insulin secretion, adiposity, and muscle mass noted in the initial osteocalcin knockout mice.[108,111-114] Hence, the consistency in the endocrine functions of osteocalcin among various species and genetic backgrounds and the full significance of these findings in humans have yet to be fully defined.

From many studies it is clear that the skeleton plays active roles in integrating organs systems and global functions within the organism, including in the control of energy metabolism. Besides osteocalcin, several other local regulators and pathways in bone, and in osteolineage cells in particular, have been linked to the regulation of systemic energy metabolism and glucose homeostasis, including the hypoxia-inducible pathway controlling osteolineage cell metabolism and skeletal glucose consumption, Wnt/β-catenin signaling, PPAR-γ activity in the osteolineage, and lipocalin and sclerostin production.[115,116]

KEY POINTS

- Mechanical forces, hormones, and the central nervous system complement the local factors discussed earlier to regulate bone formation and resorption. Receptors important for sensing mechanical forces are under active study. Osteocytes are the best studied cells that sense mechanical forces and signal to suppress sclerostin expression in response to these forces. Parthyroid hormone (PTH) increases both bone formation and resorption, whereas estrogens, glucocorticoids, and other steroid/thyroid hormones target multiple bone cell types to regulate bone turnover. The sympathetic nervous system, in response to multiple signals, can dramatically block osteoblast action. In turn, bone cells secrete a number of hormones that can affect mineral metabolism and other important physiological processes.

CONCLUSION

Bone formation during skeletal development involves complex spatiotemporal coordination among multiple molecules, cell types, and tissues. A large number of morphogens, signaling molecules, and transcriptional regulators have been implicated in the regulation of bone development. Many of the developmental mechanisms are recapitulated or remain important later in bone homeostasis and/or pathology. The skeleton is a vital organ system essential to survival and well-being. Its major functions, including mechanical support and mineral homeostasis, are achieved by continuous remodeling throughout life. Osteoclasts and osteoblasts normally act in a coordinated manner to resorb and rebuild bone. Most bone disorders are caused by bone loss resulting from an imbalance in the remodeling cycle, with bone resorption exceeding bone formation. A better understanding of the molecular mechanisms behind skeletal biology, largely derived from discoveries based on mouse and human genetics, has provided opportunities for developing therapies to treat diseases of bone. Additional advances in the molecular and genetic studies of bone, including integrative communication between pathways and cell types within and beyond the skeleton proper, may offer as yet unexplored targets for developing novel therapeutic options to treat various bone pathologies.

Calcium plays an important role in many physiologic pathways, including muscle contraction, the secretion of neurotransmitters and hormones, and the coagulation pathways, and is an important component of the skeleton.[1,2] Disturbances in extracellular calcium concentration therefore may cause a variety of symptoms, the most common of which reflect abnormal neuromuscular activity. Thus, hypercalcemia may lead to muscle weakness and areflexia, anorexia, constipation, vomiting, drowsiness, depression, confusion, other cognitive dysfunction, and coma.[2] Hypercalcemia leads to hypercalciuria, which can result in medullary calcification, nephrocalcinosis, and impaired kidney function. Hypocalcemia, conversely, may cause anxiety, seizures, muscle twitching, epilepsy, tetany, Chvostek's and Trousseau's signs, carpal or pedal spasm, stridor, bronchospasm, and intestinal cramps, as well as cataracts, basal ganglia calcifications, skeletal malformations, and abnormal dentition.[1] The control of body calcium involves a balance between the amounts that are absorbed from the gut, deposited into bone and into cells, and excreted from the kidney (Fig. 52.1). This fine balance, involving three organs, is chiefly under the control of parathyroid hormone (PTH), which is synthesized and secreted by the parathyroid glands.[1,2] Thus, hypocalcemia will lead to an increased secretion of PTH, whereas hypercalcemia will result in diminished PTH secretion. A number of clinical disorders characterized by derangements of calcium homeostasis are caused by abnormalities of the parathyroid glands themselves. Thus, PTH oversecretion attributed to parathyroid tumors, which affect 3:1000 in the general population, is a major cause of hypercalcemia, which may be associated with kidney stones, osteoporosis, and peptic ulcers. PTH deficiency resulting in hypocalcemia is thought to occur in 1:4000 live births, but precise data regarding the incidence are lacking. This chapter will review the physiologic and biochemical mechanisms underlying extracellular calcium homeostasis and the genetic basis for disorders of calcium metabolism.

KEY POINTS

- Parathyroid hormone is the most important peptide hormone for regulating calcium homeostasis. Its synthesis and secretion is controlled by the calcium-sensing receptor, a G protein–coupled receptor that is expressed in the parathyroid glands.

REGULATION OF CALCIUM HOMEOSTASIS

Distribution and Metabolic Actions of Calcium

The total-body content of calcium in a normal adult is approximately 1000 g, nearly all of which exists within the crystal structure of bone mineral, and less than 1% of which is dissolved in extracellular and intracellular fluid.[1,2] On average, bone mineral closely approximates the composition of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$), which means

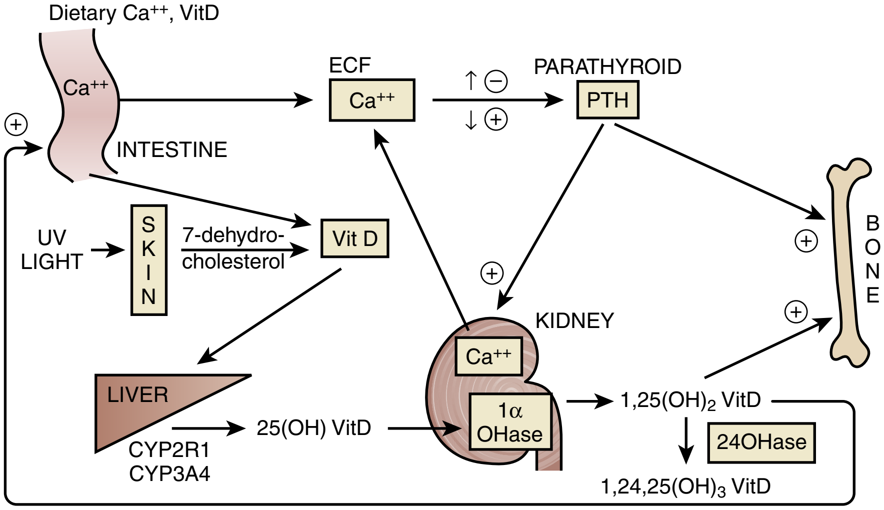

Fig. 52.1 Regulation of Extracellular Fluid (*ECF*) Calcium (Ca2^{++}) by Parathyroid Hormone (*PTH*) Action on Kidney, Bone, and Intestine. The calcium-sensing receptor (CaSR) senses a decrease in ECF Ca2^{++}, and this leads to an increase in PTH secretion, which acts directly on kidney and bone that express the PTH/PTHrP receptor (PTHR1; see Fig. 52.2). The skeletal effects of PTH are to increase (+) osteoclastic bone reabsorption, but as osteoclasts do not express the PTHR1, this action is mediated via the osteoblasts, which do have this receptor, and in response release cytokines and factors that activate osteoclasts. In the kidney, PTH stimulates (+) the 1α hydroxylase (1αOHase) to increase the conversion of 25-hydroxy vitamin D (25(OH)D) to the active metabolite 1,25-dihydroxy vitamin D (1,25(OH)$_2$D), which is subsequently inactivated by the 24-hydroxylase. In addition, PTH increases (+) the reabsorption of Ca2^{++} from the renal distal tubule and inhibits the reabsorption of phosphate from the proximal tubule, thereby leading to hypercalcemia and hypophosphatemia. PTH also inhibits Na$^+$–H$^+$ antiporter activity and bicarbonate reabsorption, thereby causing a mild hyperchloremic acidosis, and it reduces expression of two sodium-dependent phosphate cotransporters, NPT2a and NPT2c, thereby increasing urinary phosphate excretion. The elevated 1,25(OH)$_2$D acts on the intestine to increase (+) absorption of dietary calcium and phosphate, and it is important to note that PTH does not appear to have a direct action on the gut. Thus, in response to hypocalcemia and the increase in PTH secretion, all of these direct and indirect actions of PTH on the kidney, bone, and intestine will help to increase ECF Ca2^{++}, which in turn will act via the CaSR to decrease PTH secretion.

that 6 mmol of phosphate is released with every 10 mmol of calcium mobilized during bone resorption (or ~1:2 on a mg/mg basis).

In blood, 50% of calcium is bound to proteins. Albumin accounts for approximately 80% of the protein-bound fraction. Another portion (~10%) is associated with diffusable ion complexes. Thus, normally only half of total plasma calcium is freely ionized, but it is this fraction that is most important physiologically and thus subject to stringent endocrine regulation. The normal ranges of total and ionized serum calcium in the adult are 8.5 to 10.5 mg/dL and 4.25 to 5.25 mg/dL, respectively.[2] The usual 2:1 ratio of total to ionized calcium may be disturbed by disorders such as metabolic acidosis (calcium binding to proteins is reduced at acid pH) or by changes in serum protein concentrations, as in starvation, cirrhosis, dehydration, or multiple myeloma. Thus, ionized calcium concentrations can nowadays be routinely determined, if clinically required.[3]

Serum calcium is higher during infancy/childhood and adolescence than in the adult[7] but does not change at puberty or, in women, during the menstrual cycle.[2] During pregnancy, total serum calcium and albumin decline progressively, but ionized calcium is minimally affected. Fetal calcium content rises dramatically during the third trimester (to ~30 g at term), and fetal serum total and ionized calcium concentrations are higher than maternal levels, consistent with active placental transport of calcium.[4] Despite losses of 200 to 300 mg/day of calcium in breast milk, lactating women maintain normal levels of ionized calcium in blood by increasing intestinal calcium absorption in response to augmented production of 1,25-dihydroxy vitamin D (1,25(OH)$_2$D).

Calcium entry into cells is strongly favored by a steep electrochemical gradient. Thus, the cell interior is electronegative, and cytosolic free calcium is in the range of 10^{-7} M, which is 10,000-fold lower than extracellular calcium concentrations. Calcium traverses the plasma membrane through various channels, including voltage-, receptor-, and store-operated forms, the regulation of which is complex and tissue-specific.[5] Intracellularly, nearly all (99%) calcium is sequestered in pools within mitochondria, endoplasmic reticula, or sarcoplasmic reticula or is tightly bound to the inner surface of the plasma membrane. Sequestered calcium, especially that within the endoplasmic reticulum, may be released rapidly into the cytosol following activation of cell-surface receptors.[1,5] In this way, it plays a critical role in signal transduction and in controlling calcium entry via store-operated channels. The extremely low cytosolic free calcium concentration is maintained by active calcium transport into intracellular pools or by extrusion out of the cell via high-affinity, low-capacity Ca^{++}/H$^+$ ATPases and low-affinity, high-capacity Na$^+$/Ca^{++} exchangers driven by the transmembrane sodium gradient.

With the discovery of a calcium-sensing receptor (CaSR), a G protein–coupled receptor (GPCR) expressed in parathyroid, renal, epithelial, and numerous other cells, it has become clear that calcium can act as an extracellular ligand to directly control cellular function.[5] The principal actions of the CaSR with respect to calcium homeostasis include suppression of PTH secretion and, in the thick ascending loop of the renal tubule, inhibition of calcium, magnesium, and NaCl reabsorption.[5] Extracellular calcium also is used directly for normal matrix mineralization in bone and cartilage and is required for activation of important circulating or extracellular enzymes and proteases. Intracellular calcium exerts a broad range of effects via interaction with key enzymes and effector molecules, including kinases, phosphatases, calmodulins, transcription factors, ion channels (including calcium channels), and troponins and other proteins involved in contraction, microtubule and microfilament assembly, and motility.[5] The steep gradients between intracellular calcium and both extracellular and intracellular sequestered calcium are crucial for normal neuromuscular activity and provide the potential required for rapid transients and waves of cytosolic free calcium that serve key second-messenger functions in both excitable and nonexcitable cells.

Calcium Absorption

Intestinal calcium absorptive efficiency in humans ranges broadly between 20% and 70%, declines with age, and is strongly influenced by previous calcium intake, the presence of other nutrients, pregnancy, lactation, overall calcium balance, and the availability of activated vitamin D. Fecal calcium includes the residual fraction of dietary calcium that is not absorbed, as well as a contribution from secreted calcium present in bile and other digestive juices ("endogenous fecal calcium"). Endogenous fecal calcium in humans normally amounts to 100 to 200 mg/day and is relatively unaffected by changes in dietary or serum calcium.

Intestinal calcium absorption is adjusted physiologically in response to variations in calcium intake, as shown by radiocalcium kinetic and balance studies in normal subjects. Obligate renal and intestinal excretion of calcium is such that calcium balance cannot be maintained if dietary calcium consistently falls below 200 to 400 mg/day, even though the percentage of calcium absorbed may be very high (i.e., 70%). As calcium intake increases, overall calcium absorption (in mg/day) rises, but the fractional absorption of ingested calcium declines progressively such that, within the physiologic range of calcium intake, total net calcium absorption tends to plateau at approximately 400 mg/day. Consequently, urinary calcium excretion tends also to plateau at higher intakes. Additional buffering of changes in dietary calcium results from control of renal tubular calcium reabsorption and skeletal calcium release, but regulation of intestinal absorptive efficiency is critical for calcium balance. The mechanisms of this inverse regulation of intestinal absorptive efficiency by changes in calcium availability are considered further later in the chapter.

Mechanisms and Sites of Calcium Absorption

Calcium is absorbed throughout the intestine. In terms of rates of transport per unit length of mucosa, absorption is most efficient in the duodenum and proximal jejunum, which exhibit the highest levels of vitamin D–dependent calcium-binding proteins and in which lower luminal pH promotes dissociation of calcium from complexes with food constituents and other ions. On the other hand, longer residence times in the more distal small bowel segments may allow absorption of a larger proportion of total calcium intake in the distal jejunum and ileum. The ileum, for example, may become an important site of net calcium absorption during dietary restriction of calcium or when the residence time of luminal contents in more proximal bowel segments is reduced.

Calcium is absorbed by both a passive, paracellular route and by an active, transcellular mechanism. Paracellular absorption predominates at higher levels of dietary calcium, whereas transcellular absorption, which is strongly upregulated by activated vitamin D, is most important when dietary calcium is limiting. Transcellular calcium absorption necessarily involves three steps: entry into the cell, diffusion across the cell, and extrusion from the cell (see Chapter 50). The first step, entry through the apical brush border, occurs via a member of the vanilloid (TRPV) superfamily of channels, namely TRPV6.[6] Another closely related member of this family, TRPV5 (formerly ECaC1 or CaT2), appears to be dominantly involved in calcium reabsorption in the distal renal tubules (see later). The genes encoding TRPV6 and TRPV5 are located on chromosome 7q33-35, and the protein structure includes six transmembrane regions, a short hydrophobic region between segments 5 and 6 that likely forms the calcium pore, and large intracellular domains at the N- and C-terminals. The pore region is highly selective for calcium,[7] and mutations in this region have been shown to abolish calcium permeability.[8] Posttranslational modification and glycosylation of TRPV6 occurs, but the functional effects of these modifications are not well defined. Similarly, the mechanisms regulating the activity of these molecules are not well understood. *TRPV6* and *TRPV5* expression varies significantly among species and in humans, and both genes are expressed in a variety of tissues.[9] Specifically, TRPV5 seems to be the major isoform expressed in the kidney, while TRPV6 is most highly expressed in the small intestine (restricted to the apical surface of epithelial cells). Given the important role of $1,25(OH)_2D$ and other hormonal regulators in calcium absorption, the effects of these hormones on TRPV6 expression have been investigated. $1,25(OH)_2D$ increases TRPV6 expression[10] (see Chapter 50). Furthermore, mice with targeted inactivation of the vitamin D receptor demonstrate a 90% reduction in TRPV6 expression and a threefold reduction in intestinal calcium absorption.[11] Additionally, calcium exposure appears to independently affect TRPV6 expression because high calcium intake decreases TRPV6 expression, and low intake increases it. Finally, TRPV6 expression is decreased in mice with targeted inactivation of their estrogen receptor-α gene and is increased in mice receiving exogenous estradiol administration.[12]

After calcium has entered the cell, it must be transported through the cytoplasm and extruded from the cell against a steep gradient. The mechanism by which calcium moves through the cell involves the small cytosolic protein calbindin D9k. Calcium entering the cell via the apical TRPV6 channel becomes tightly associated with the calbindin, which buffers the relatively large mass of entering calcium and minimizes its impact upon cytosolic free calcium concentrations. The calbindin/calcium complex then diffuses across the cytosol to the basolateral membrane. Free calcium then dissociates into the low-cytosolic calcium environment maintained immediately subjacent to the basolateral membrane by high-affinity membrane Ca^{++}-ATPases located there. Finally, these calcium ATPases actively extrude calcium out of the cell. The known cellular concentrations and kinetic properties of the calbindin D9k molecule would support observed rates of duodenal calcium transport at submicromolar concentrations of cytosolic free calcium. Indeed, the importance of this buffered diffusional process predicts that enterocyte calbindin D9k content is likely to be a major determinant, along with TRPV6 activity, of the overall rate of enterocyte calcium transport.

Renal Calcium Excretion

Regulation of renal calcium excretion is an important mechanism for homeostatic control of blood ionized calcium in the face of fluctuations in filtered load, as derived from intestinal calcium absorption and net bone resorption.[5] When urinary calcium is viewed as a function of the amount of calcium actually absorbed by the gut (i.e., after regulation of intestinal absorptive efficiency has been factored out), the precision with which the kidney adjusts tubular calcium reabsorption to residual changes in filtered load becomes obvious. Ordinarily, the daily load of calcium filtered at the glomerulus (the product of glomerular filtration rate and ultrafilterable calcium) is approximately 10,000 mg/day in adult humans, which means that the extracellular calcium pool is completely filtered several times per day. As urinary calcium excretion (and net intestinal calcium absorption) is approximately 200 mg/day, only 2% of filtered calcium is excreted normally. This high ratio of filtered calcium to excreted calcium affords ample opportunity for finely tuned hormonal control of calcium excretion, even though it may be difficult to measure the small changes involved.

Sites and Mechanisms of Renal Calcium Reabsorption

Calcium is reabsorbed at multiple sites and by different mechanisms along the nephron.[5] As in the intestine, the challenge of transporting calcium across the renal epithelium requires that adequate rates of transport be achieved without substantially increasing the concentration of calcium within the cytosol of the epithelial cell. This is accomplished mainly by use of paracellular diffusional mechanisms that are supplemented, in some nephron segments, by active transcellular transport, especially in response to hormonal stimulation.

Approximately 60% to 70% of tubular calcium reabsorption, like that of sodium, occurs in the proximal tubule. Proximal tubular calcium reabsorption occurs mainly via passive diffusion along paracellular pathways, down the ambient (lumen-positive) electrochemical gradient. Another 20% to 25% of the filtered calcium load is reabsorbed in Henle's loop. This occurs mainly by paracellular diffusion in the cortical thick ascending limb (cTAL), although active transcellular transport may play a minor role as well. Calcium (and magnesium) reabsorption in this segment is severely impaired in patients with homozygous inactivating mutations in claudin 16 (CLDN16), previously referred to as *paracellin-1,* or claudin 19 (CLDN19), which are specifically expressed in tight junctions of the cTAL and are presumably required for normal divalent cation conductance.[5,13] Hypercalcemia suppresses renal tubular calcium reabsorption, even in the absence of PTH, an effect attributable to direct activation of basolateral CaSRs in the cTAL (and possibly other nephron segments). In the cTAL, activated CaSRs lower apical K^+ exit by inhibiting renal outer medullary K^+ channels (ROMKs), thereby blunting Na-K-2Cl co-transporter (NKCC2) activity and reducing the transepithelial voltage gradient that drives paracellular cation movement.[14] The critical importance of normal rates of Na-K-2Cl reabsorption for adequate calcium transport in the cTAL is highlighted clinically by the occurrence of dramatic hypercalciuria in patients with Bartter syndrome, which involves defects in NKCC2, ROMK, or other transporters or channels required for effective Na-K-2Cl reabsorption.[14] An analogous Bartter-like phenotype may occur in some patients with activating CaSR mutations.[15] CaSR activation in the cTAL also antagonizes PTH-stimulated increases in calcium reabsorption, possibly by impairing cyclic adenosine monophosphate (cAMP) generation (see later).

Only approximately 8% to10% of filtered calcium is reabsorbed in more distal segments of the tubule, but calcium transport in the distal nephron is a key control point for hormonal regulation and involves predominantly transcellular reabsorption.[5] Cells in the late distal tubule exhibit striking colocalization of several unique proteins that are critical for effective transcellular calcium reabsorption. These include an apical epithelial calcium channel, TRPV5, the cytosolic calcium-binding protein calbindin-D28K, basolateral plasma membrane calcium ATPase(s) (PMCAs), and basolateral Na^+/Ca^{++} exchanger-1 (NCX1).[16,17] As in the intestinal epithelium, these cells admit calcium across their apical membranes via opening of TRPV5. Expression of this channel is upregulated by PTH, thus enhancing calcium-reabsorption (see later). PTH also increases calbindin-D28K levels, which enhances transcellular calcium reabsorption via increased buffering of subapical Ca^{++} ions. Calcium bound to calbindin-D28K is ferried across the cell to the basolateral membrane, where it ultimately is extruded against a steep electrochemical gradient, predominantly via NCX1 (70% of Ca^{++} flux) but also by PMCA. As expected, mice with a TRPV5 mutation or deficiency[18] or lacking calbindin D28K[19] manifest severe hypercalciuria.

Additional calcium reabsorption may occur in more distal nephron segments, such as cortical and medullary collecting ducts. Proteins other than those described earlier may be involved in renal calcium reabsorption as well, including voltage-operated calcium channels and Cl– channels, as evidenced by the hypercalciuria seen in Dent's disease, an X-linked disorder caused by inactivating mutations in the Cl– channel ClC–5, which may be involved in endocytic vesicle function and protein trafficking.[20,21]

Regulation of Renal Calcium Reabsorption

Calcium excretion is affected by a variety of hormones, ions, nutrients, and drugs. Among these, PTH is the principal physiologic regulator of renal tubular calcium transport, as appreciated clinically by the markedly abnormal overall relation of serum to urinary calcium in hyperparathyroidism and hypoparathyroidism, and the reduction in calcium excretion observed after injection of PTH in healthy individuals or in patients affected by pseudohypoparathyroidism.[22] PTH acts to enhance tubular calcium reabsorption in the cTAL, distal convoluted tubules (DCT), and connecting tubules (CNT). It augments DCT calbindin-D28K expression[23] and basolateral Na^+/Ca^{++} exchange, increases the affinity for calcium of the basolateral Ca^{++}-ATPase, and hyperpolarizes the DCT cell, which then activates the TRPV5 channel.[24] In immortalized murine distal tubular cells, PTH causes insertion into the apical membrane of new dihydropyridine-sensitive membrane calcium channels, and it stimulates stretch-activated nonselective cation channels in rabbit CNT. These are distinct from TRPV5 channels and may represent other mechanisms of apical calcium entry. PTH increases the surface expression or activity of TRPV5 epithelial calcium channels. In the cTAL, PTH also may increase some form of active transcellular transport, and it may stimulate paracellular, diffusional calcium transport by augmenting the transepithelial voltage gradient, at least in some segments and species.

Studies in patients with inactivating vitamin D receptor mutations have demonstrated that $1,25(OH)_2D$ is required for the calcium-reabsorptive response to PTH. It furthermore accelerates the increase in DCT cell calcium entry initiated by PTH and directly increases DCT calcium reabsorption, apparently by driving higher expression of TRPV5, calbindin D28K, and PMCA[25] (see Chapter 50). Other hormones that affect calcium reabsorption include calcitonin, which, when given in large doses, acutely reduces proximal tubular calcium reabsorption by a mechanism independent of PTH; however, an important role for calcitonin in the physiologic regulation of calcium reabsorption is thought to be unlikely. Hypercalciuria observed in states of excess growth hormone or cortisol seems likely to be secondary to an increased filtered load of calcium rather than to direct tubular actions of these hormones. Estrogen treatment of normal postmenopausal women lowers urinary calcium excretion by increasing tubular calcium reabsorption. In DCT of ovariectomized rats, 17β-estradiol acutely increases mRNA expression of all major components of the calcium-transport pathway, including TRPV5, calbindin D28K, NCX1, and PMCA1b.[26] Reported effects on tubular calcium reabsorption of insulin, glucagon, antidiuretic hormone, and angiotensin II[27] are of uncertain physiologic or clinical significance.

PTH GENE STRUCTURE AND FUNCTION

The *PTH* gene is located on chromosome 11p15 and consists of three exons. Exon 1 is untranslated, whereas exons 2 and 3 encode the 115–amino acid pre-proPTH peptide (see Chapter 47) and the 3′ untranslated region. The 5′ regulatory sequence of the human *PTH* gene contains a vitamin D response element 125 bp upstream of the transcription start site, which downregulates PTH mRNA transcription in response to vitamin D receptor binding. *PTH* gene transcription (as well as PTH peptide secretion) is also dependent upon the extracellular calcium and phosphate concentration, although the presence of a specific upstream "calcium or phosphate response element(s)" has not yet been demonstrated. The secretion of mature PTH, which is an 84-amino acid peptide, from the parathyroid chief cell is regulated through the CaSR, which is also expressed in the renal tubules and in numerous other tissues, albeit at lower abundance.[1,2,5,28] PTH mRNA is first translated into a pre-proPTH peptide. After the mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of approximately 2 minutes, via nonsaturable hepatic and renal uptake (see also Chapter 47).

KEY POINTS

- The widely expressed parathyroid hormone (PTH)/parathyroid hormone–related peptide (PTHrP) receptor (PTHR1), a G protein–coupled receptor, mediates the actions of PTH and PTHrP. Because of its dual roles, *PTHR1* mutations affect mineral ion homeostasis as well as chondrocyte differentiation, and thus bone growth.

PTH mediates its actions through a receptor that it shares with PTH-related peptide (PTHrP, also known as PTHLH or PTH-like hormone).[1,5] This PTH/PTHrP receptor (Fig. 52.2), a GPCR whose gene is located on chromosome 3p21.3, is highly expressed in kidney and bone, where it mediates the endocrine actions of PTH. However, during embryonic and postnatal development, the PTH/PTHrP receptor is most abundantly expressed in chondrocytes of the metaphyseal growth plate, where it mediates predominantly the autocrine/paracrine actions of PTHrP.[29] Mutations involving the genes that encode PTH, the CaSR, the PTH/PTHrP receptor, AP2S1, Gα11, and G$_s\alpha$ all affect the regulation of calcium homeostasis and can thus be associated with genetic disorders characterized by hypercalcemia or hypocalcemia (Table 52.1).

KEY POINTS

- Studies of syndromic and nonsyndromic forms of primary hyperparathyroidism and hypoparathyroidism, which may occur as hereditary (i.e., familial) or nonfamilial (i.e., sporadic) diseases, have helped to identify some of the genetic abnormalities involved in the parathyroid tumorigenesis and in the embryonic development of the parathyroid glands.

HYPERCALCEMIC DISEASES

Genetic disorders resulting in hypercalcemia may be associated with parathyroid tumors, disorders of the CaSR or PTH/PTHrP receptors, impaired 1,25(OH)$_2$D inactivation, or chromosomal deletion syndromes (e.g., Williams syndrome).[2,30]

Parathyroid Tumors

Similar to the findings in other tumors, the abnormal expression of an oncogene or the loss of a tumor suppressor gene can result in an abnormal proliferative activity of parathyroid cells, and the molecular exploration of these genes has provided important novel insights into the pathogenesis of different forms of hyperparathyroidism.

Genetic abnormalities involving one of 12 genes may be found in approximately 10% of patients with parathyroid tumors, giving rise to primary hyperparathyroidism (PHPT), and resulting in syndromic and nonsyndromic forms of PHPT, which may occur as hereditary (i.e., familial) disorders or as nonfamilial (i.e., sporadic) diseases.[30,31] However, the distinction between sporadic and familial forms in PHPT patients is sometimes difficult because a family history may be absent in some sporadic cases, as the parent with the disease may not have been investigated or may have died before PHPT symptoms developed; or the PHPT may be attributed to a *de novo* germline mutation in the patient, which would account for an absent family history, but results in an increased risk for hereditary PHPT in the children of the patient. Syndromic forms of PHPT may occur as part of complex disorders (e.g., as part of multiple endocrine neoplasia [MEN] syndromes) and be inherited as autosomal dominant traits, (Table 52.1).[30,32] Such syndromic PHPT forms are MEN1, MEN2, MEN3 (also referred to as MEN2b), MEN4, and the hyperparathyroidism–jaw tumor (HPT-JT) syndrome.[30,32,33] PHPT as a nonsyndromic isolated endocrinopathy may occur as a familial disorder, which is referred to as *familial isolated hyperparathyroidism* (FIHP), or as a nonfamilial (sporadic) disorder.[30,32]

KEY POINTS

- So far, only approximately 10% of all patients with primary hyperparathyroidism have a defined mutation in one of 12 genes known to be associated with hyperparathyroidism. However, testing for mutations in these genes will help to confirm the diagnosis of a syndromic or nonsyndromic form of primary hyperparathyroidism, and thereby help in the clinical management and treatment of the disorder in patients and their relatives.

Syndromic Forms of Primary Hyperparathyroidism

Multiple Endocrine Neoplasia Type 1. MEN type 1 (MEN1) is characterized by the combined occurrence of tumors of the parathyroid glands, pancreatic islet cells, and anterior pituitary gland.[30,32] Parathyroid tumors occur in 95% of MEN1 patients, and the resulting hypercalcemia is the first manifestation of MEN1 in approximately 90% of patients. Pancreatic islet cell tumors occur in 40% of MEN1 patients and gastrinomas, leading to Zollinger–Ellison syndrome, are the most common type and also the important cause of morbidity and mortality in MEN1 patients. Anterior pituitary tumors occur in 30% of MEN1 patients, with prolactinomas representing the most common type. Associated tumors, which may also occur in MEN1, include adrenal cortical tumors, carcinoid tumors, lipomas, and cutaneous angiofibromas and collagenomas. The gene causing MEN1 is located on chromosome 11q13 and consists of 10 exons that encode a 610–amino acid protein referred to as *menin*. Over 1100 germline *MEN1* mutations have been identified, and the majority (>80%) are inactivating, consistent with its role as a tumor suppressor gene.[32,34] These mutations are diverse in their types: approximately 25% are nonsense, approximately 45% are frameshift deletions or insertions, approximately 9% are splice-site mutations, approximately 20% are missense mutations, and approximately 1% are whole or partial gene deletions.[30,34] In addition, *MEN1* mutations are scattered throughout the 1830-bp coding region of the genes with no evidence for clustering. Correlations between the MEN1 germline mutations and the clinical manifestations of the disorder appear to be absent.[34] Tumors from MEN1 patients and non-MEN1 patients have been observed to harbor the germline mutation together with a somatic loss of heterozygosity (LOH) involving chromosome 11q13, as expected from Knudson's model and the proposed role of the *MEN1* gene as a tumor suppressor.[34]

Menin is a nuclear protein in nondividing cells that interacts with a number of proteins that are involved in transcriptional regulation, genome stability, cell division, and proliferation[34,35] (see Chapter 133).

Multiple Endocrine Neoplasia Type 2 and Type 3. MEN type 2 (MEN2) describes the association of medullary thyroid carcinoma (MTC), pheochromocytomas, and parathyroid tumors.[30,32,33] Three clinical variants of MEN2 are recognized: MEN2a, MEN2b (also referred

Fig. 52.2 Schematic Representation of Some of the Components Involved in Calcium Homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (*CaSR*), which is a 1078–amino acid G protein–coupled receptor (*GPCR*). The PTH/PTHrP receptor, which mediates the actions of PTH and PTHrP, is also a GPCR. Thus, Ca^{++}, PTH, and PTHrP involve signaling pathways requiring an interaction between receptors that specifically recognize these ligands and couple to different G proteins, including $G\alpha s$, $G\alpha i$, and $G\alpha q/\alpha 11$, respectively. $G\alpha s$ couples to the adenylyl cyclase (*AC*), which catalyzes the formation of cAMP from ATP. $G\alpha i$ inhibits AC activity. cAMP stimulates PKA, which phosphorylates cell-specific substrates. Activation of the $G\alpha q/\alpha 11$ pathway stimulates PLC, which catalyzes the hydrolysis of the phosphoinositide (*PIP2*) to inositol triphosphate (*IP3*), which increases intracellular calcium, and diacylglycerol (*DAG*), which activates PKC. These proximal signals modulate downstream pathways, which result in specific physiologic effects. Abnormalities in several genes, which lead to mutations in proteins in these pathways, have been identified in specific disorders of calcium homeostasis (see Table 52.1).

to as MEN3), and MTC-only. MEN2a is the most common variant, and the development of MTC is associated with pheochromocytomas (50% of patients), which may be bilateral, and parathyroid tumors (20% of patients). MEN2b, which represents 5% of all MEN2 cases, is characterized by the occurrence of MTC and pheochromocytoma in association with a Marfanoid habitus, mucosal neuromas, medullated corneal fibers, and intestinal autonomic ganglion dysfunction leading to multiple diverticula and megacolon. Parathyroid tumors do not usually occur in MEN2b. MTC-only is a variant in which medullary thyroid carcinoma is the sole manifestation of the syndrome. The gene causing all three MEN2 variants is located on chromosome -10q11.2, and is the *RET* protooncogene, which encodes a tyrosine kinase receptor with cadherin-like and cysteine-rich extracellular domains, and a tyrosine kinase intracellular domain. Specific mutations of *C-RET* have

been identified for each of the three MEN2 variants. Thus, in 95% of patients, MEN2a is associated with mutations of the cysteine-rich extracellular domain, and mutations in codon 634 (Cys→Arg) account for 85% of MEN2a mutations.[33] However, a search for *C-RET* mutations in sporadic non-MEN2a parathyroid adenomas revealed no codon 634 mutations. MTC-only is also associated with missense mutations in the cysteine-rich extracellular domain, and most mutations are in codon 618. However, MEN2b is associated with mutations in codon 918 (Met→Thr) of the intracellular tyrosine kinase domain in 95% of patients. Interestingly, the *C-RET* protooncogene is also involved in the etiology of papillary thyroid carcinomas and in Hirschsprung disease. Mutational analysis of *C-RET* to detect mutations in codons 609, 611, 618, 634, 768, and 804 in MEN2a and MTC-only, and codon 918 in MEN2b, has been used in the diagnosis and management of patients and families with these disorders.[33] Indeed, the utilization of a genetic diagnosis has dramatically improved the outcomes for patients who are at risk for MTC and have undergone prophylactic thyroidectomy. Thus, the 10-year survival in patients with metastatic MTC is approximately 20%, but approximately 90% of young patients with a *C-RET* mutation who had a prophylactic thyroidectomy have no evidence of persistent or recurrent MTC at 7 years after surgery.[33,36]

Multiple Endocrine Neoplasia Type 4. Approximately 5% to 10% of patients with MEN1 do not have mutations of the *MEN1* gene,[32,34] and these patients may have mutations involving other genes. One of these genes is *CDNK1B*, which is located on chromosome 12p13, and encodes the 196–amino acid cyclin-dependent kinase inhibitor (CDKI) p27^{kip1} that regulates the cell cycle. Approximately 3% of these patients with MEN1–associated tumors, such as parathyroid adenomas, pituitary adenomas, and pancreatic NETs in association with gonadal, adrenal, renal, and thyroid tumors have *CDNK1B* mutations, and these patients are referred to as having MEN type 4 (MEN4).[37] To date, over 15 different heterozygous loss-of-function *CDNK1B* mutations, consistent with MEN4 being an autosomal dominant-disorder, have been identified in less than 50 patients with MEN4.[30,37] Germ line *CDNK1B* mutations may also rarely be found in patients with sporadic (i.e., nonfamilial) forms of primary hyperparathyroidism.[38]

The Hyperparathyroidism–Jaw Tumor Syndrome. The HPT-JT syndrome is an autosomal dominant disorder characterized by the development of parathyroid adenomas and carcinomas, and fibroosseous jaw tumors.[30,31] In addition, some patients may also develop uterine tumors and renal abnormalities, which include Wilms tumors, renal cysts, renal hamartomas, renal cortical adenomas, and papillary renal cell carcinomas. Other tumors, including pancreatic adenocarcinomas, testicular mixed germ cell tumors with a major seminoma component, and Hürthle cell thyroid adenomas, have also been reported in some patients.[31] It is important to note that the parathyroid tumors may occur in isolation and without any evidence of jaw tumors, and this may cause confusion with other hereditary hypercalcemic disorders such as MEN1, familial benign hypercalcemia (FBH), which is also referred to as familial hypocalciuric hypercalcemia (FHH), and FIHP.[30] HPT-JT syndrome can be distinguished from FBH, as FBH serum calcium levels are elevated during the early neonatal or infantile period, whereas in HPT-JT such elevations are uncommon in the first decade.[30] In addition, HPT-JT patients, unlike FBH patients, will have associated hypercalciuria. The distinction between HPT-JT patients and MEN1 patients, who have only developed the usual first manifestation of hypercalcemia (>90% of patients), is more difficult and is likely to be influenced by operative and histological findings, as well as by the occurrence of other characteristic lesions in each disorder. It is important to note that HPT-JT patients will usually have single adenomas or a carcinoma, whereas MEN1 patients will often have multiglandular parathyroid disease. The distinction between FIHP and HPT-JT in the absence of jaw tumors is difficult but important, as HPT-JT patients may be at a higher risk of developing parathyroid carcinomas.[30] These distinctions may be helped by the identification of additional features, and a search for jaw tumors and renal, pancreatic, thyroid, and testicular abnormalities may help to identify HPT-JT patients. The jaw tumors in HPT-JT are different from the brown tumors observed in some patients with primary hyperparathyroidism and do not resolve after parathyroidectomy.[31] Indeed, ossifying fibromas of the jaw are an important distinguishing feature of HPT-JT from FIHP, and the occurrence of these may occasionally precede the development of hypercalcemia in HPT-JT patients by several decades. The gene that causes HPT-JT is located on chromosome 1q31.2 and consists of 17 exons that encode a ubiquitously expressed and evolutionary conserved 531–amino acid protein, designated parafibromin.[39] This gene is also referred to as *CDC73* or *HRPT2* (i.e., hyperparathyroidism type 2). Over 60 heterozygous *HRPT2* germline mutations associated with HPT-JT have been reported, and these are scattered throughout the 1593-bp coding region, with the majority (>80%) predicting a functional loss through premature truncation.[30,31] A genotype–phenotype correlation was not apparent from these analyses.[31,39,40] The observation of LOH involving the chromosome 1q21.32 region in HPT-JT–associated tumors indicated that parafibromin may be acting as a tumor suppressor, consistent with Knudson's two-hit hypothesis.[31,39] Similar germline and somatic *HRPT2* mutations have also been found in sporadic parathyroid carcinomas, and the frequency of such mutations is high, ranging from 67% to 100%[31,40]; however, the frequency of *HRPT2* mutations in sporadic parathyroid adenomas is low, at 0% to 4%, indicating that *HRPT2* mutations likely confer an aggressive growth potential to the parathyroid cells.[31,34,39,40] *HRPT2* mutations and allelic imbalances have also been identified in sporadic renal tumors, and a loss or downregulation of *HRPT2* expression has been reported in both breast and gastric cancers.[31] These studies indicate that *HRPT2* and its encoded protein, parafibromin, play a critical role in inherited and sporadic parathyroid cancers, as well as other nonhereditary solid tumors. Parafibromin, which is predominantly a nuclear protein and a component of the polymerase-associated factor-1 (PAF-1) complex, likely has roles in transcriptional events that include histone modification, chromatin remodeling, initiation, and elongation.[31,34,41] Studies of a mouse deleted for *Hrpt2* have revealed that Hrpt2 expression and the parafibromin/PAF complex directly regulate genes (e.g., *H19, IgF1, Ifg3, Igfbp4, Hmga1, Hmga2*, and *Hmga3*) that are involved in cell growth and apoptosis.[42]

Nonsyndromic Forms of Primary Hyperparathyroidism

Familial Isolated Hyperparathyroidism. FIHP may represent an incomplete manifestation of a syndromic form such as MEN1, HPT-JT, or FHH because FIHP caused by germline mutations of the *MEN1*, *HRPT2 (CDC73),* or *CaSR* genes, respectively, has been reported in over 40 kindreds.[30,31,39] The sole occurrence of parathyroid tumors in these syndromic disorders is remarkable, and the mechanisms that determine the altered phenotypic expressions of these mutations remain to be authenticated. However, it is important to note that the genetic etiology of nonsyndromic FIHP in the majority of families remains to be elucidated.[31,34,43] Thus, search in 32 kindreds with nonsyndromic FIHP for mutations of the *MEN1*, *CaSR,* and *HRPT2* genes have revealed that only one family harbored a germline mutation, and this involved the *HRPT2* gene that encodes parafibromin.[43] Activating variants of the glial cells missing 2 (*GCM2*) gene, which encodes a parathyroid-specific transcription factor, have also been identified in some FIHP patients.[44,45] However, studies of other FIHP kindreds have indicated that another locus, referred to as *HRPT3,* on chromosome 2p13.3-p14, is likely to be involved in the etiology of nonsyndromic FIHP.[31] Thus, the genes and their underlying abnormalities that lead to nonsyndromic FIHP remain to be identified.

Nonfamilial (Sporadic) Primary Hyperparathyroidism Owing to Germline Mutations. Nonfamilial (sporadic) forms of PHPT may be associated with germline mutations involving the *MEN1*, *CDC73*, *CaSR*, *CDKIs*, or *PTH* genes. Thus, approximately 10% of patients presenting younger than 45 years of age with nonfamilial (sporadic) PHPT may have a *de novo* germline *MEN1, CDC73*, or *CaSR* mutation,[30-32] and this has implications for their future management, in requiring screening for the occurrence of tumors associated with the specific syndrome, as well as for screening their children who may inherit the germline mutation. Moreover, more than 5% of patients with typically presenting PHPT in the sixth to ninth decades of life with solitary parathyroid adenomas and without family histories of parathyroid, MEN, or other endocrine tumor syndromes may have germline mutations of genes encoding CDKIs; (CDKN1A (p21), CDKN2B (p15), or CDKN2C (p18)), thereby indicating that rare variants of these CDKIs may contribute to the etiology of nonfamilial (sporadic) PHPT, as reduced-penetrance predisposition alleles.[46] In addition, a nonsense mutation, Arg83Stop, has been reported that truncates the secreted PTH after the 52nd amino acid and occurred in association with LOH of the *PTH* locus in a parathyroid adenoma.[47] The patient, who had presented with hypercalcemia and an undetectable serum intact PTH concentration (measured by two-site sandwich assays), showed heterozygosity, with wild-type and mutant alleles present in the peripheral-blood leukocytes, which is consistent with a germline *PTH* mutation, but the parathyroid adenoma had a loss of the wild-type allele, while the mutant allele was retained. Following removal of the parathyroid adenoma, normocalcemia was restored.[47] These findings demonstrate that *PTH* nonsense mutations, which result in truncated forms of PTH not recognizable by standard hormone assays, may be associated with parathyroid adenoma and that endogenously produced N-terminal PTH fragments can be biologically active.

Somatic Abnormalities in Sporadic Parathyroid Tumors. Nonsyndromic sporadic parathyroid tumors may harbor somatic abnormalities of the *MEN1*, cyclin D1 (*CCND1*)/*PTH*, *GCM2*, retinoblastoma (*RB*), and retinoblastoma-interacting zinc finger protein (*RIZ1*) genes; and the LRP5 and Wnt/β-catenin pathway.[31,48] Whole-exome sequence analysis of sporadic parathyroid adenomas has identified that 35% to 50% of these tumors have a somatic mutation involving the *MEN1* gene, indicating that this is a major driver for tumorigenesis. Somatic rearrangements that juxtapose *CCND1*, an important cell-cycle regulator, and the 5′-PTH regulatory elements are found in at least 15% of sporadic parathyroid adenomas; this genetic rearrangement was previously referred to as parathyroid adenoma 1 and is associated with overexpression of cyclin D1. In addition, whole-exome sequencing of parathyroid carcinomas has revealed that greater than 45% harbor somatic *CDC73* mutations, approximately 30% have *CCND1* amplification, and greater than 20% have activation of the PI3K/AKT/mTOR pathway.[49] Allelic deletion of the *RB* gene has also been demonstrated in all parathyroid carcinomas and in 10% of parathyroid adenomas and was accompanied by abnormal staining patterns for the Rb protein in 50% of parathyroid carcinomas, but in no parathyroid adenomas. The Rb protein interacts with RIZ1, and 25% to 35% of parathyroid tumors are reported to have had LOH of the RIZ1 locus or hypermethylation of the RIZ1 promoter region, respectively.[31] Investigation of the Wnt-signaling pathway in parathyroid tumors has revealed that over 85% of adenomas and 100% of tumors from chronic renal failure patients have a shorter *LRP5* transcript, which encodes an in-frame deletion of 142 amino acids (residues 666 to 809) that encompasses the third YWTD beta propeller domain, and that this internally truncated LRP5 receptor is associated with activation of the β-catenin signaling in parathyroid tumors.

Gene Testing for Primary Hyperparathyroidism in Clinical Practice

Genetic testing for germline mutations, which are found in approximately 10% of all PHPT patients, is helpful in clinical practice in several ways, including: (1) confirmation of the clinical diagnosis so that appropriate screening for associated tumors can be undertaken; (2) implementation of appropriate treatment, such as early parathyroidectomy for patients with HPT-JT syndrome because of increased occurrence of parathyroid carcinomas, avoidance of minimally invasive parathyroid surgery in MEN1 patients who generally have multigland disease requiring open neck exploration, early prophylactic thyroidectomy in MEN2/MEN3 patients, and avoidance of surgery in FHH patients; (3) identification of family members who may be asymptomatic but harbor the mutation and therefore require screening for tumor detection and early/appropriate treatment; and (4) identification of the 50% of family members who do not harbor the familial germline mutation and can therefore be reassured and alleviated of the burden of anxiety about developing tumors.[30,32] This latter aspect cannot be overemphasized, as it helps to reduce the cost to individuals and their children, and also to health services in not having to undertake unnecessary biochemical and radiologic investigations.[30,32] Moreover, a notable example of the improvements in patient outcome resulting from genetic testing is provided by the results of prophylactic thyroidectomy in MEN2/MEN3 patients. Thus, the 10-year survival in patients with metastatic MTC is approximately 20%, and prophylactic thyroidectomy to prevent MTC and its metastases is recommended in patients with a *RET* mutation.[33] Prophylactic thyroidectomy has dramatically improved outcomes in MEN2/MEN3 patients, such that approximately 90% of young patients with a *RET* mutation who had prophylactic thyroidectomy have no evidence of persistent or recurrent MTC at 7 years after surgery.[33,36]

Indications for Mutational Analysis in Primary Hyperparathyroidism

Indications for testing for germline mutations in PHPT patients include: (1) PHPT occurring before 45 years of age, (2) multigland disease, (3) parathyroid carcinoma or atypical parathyroid adenomas (e.g., with fibrous bands or cysts), (4) being a first-degree relative of a known mutation carrier, and (5) being an index case with two or more MEN syndrome–associated endocrine tumors.[30,32] Genetic testing should use DNA obtained from leukocytes or salivary cells (i.e., nontumor cells), as DNA from parathyroid tumors is not clinically useful for establishing the diagnosis or staging, because such tumors may contain multiple mutations.[50,51]

Clinical Approach to Gene Testing in a Patient With Primary Hyperparathyroidism

A clinical approach to genetic testing in a patient who has PHPT and no manifestations of MEN-associated tumors or tumors associated with HPT-JT is as follows (Fig. 52.3).[30,32] PHPT patients in whom there is a high suspicion of a genetic etiology (e.g., young age of onset, multigland disease, parathyroid carcinoma, atypical parathyroid adenoma) should be offered genetic counseling and germline mutation testing of the *MEN1, CaSR, AP2S1, GNA11, CDC73, CDKN1A, CDKN1B, CDKN2B, CDKN2C, RET, GCM2*, and *PTH* genes using DNA obtained from nontumor cells (e.g., leukocytes).[30,32,33] Such patients may have *de novo* mutations, which occur in approximately 10% of patients, or they may have an undisclosed family history for the disease.[30,32] Furthermore, PHPT may be the first manifestation of MEN1 and HPT-JT in approximately 90% and greater than 95% of patients, respectively, with these disorders.[30,32] In addition, the clinical distinction between PHPT and FHH may be difficult, as approximately 20% of FHH patients may have elevated serum PTH concentrations and calcium:creatinine clearance of greater than 0.01,[5,30,32,52,53] and some PHPT patients may have hypocalciuria. Moreover, PHPT and familial PHPT (i.e., FIHP) may occasionally be caused by *CaSR* mutations.[5] The identification of a germline mutation should prompt entry into appropriate periodic clinical, biochemical, and radiologic screening programs, for example, for MEN- and HPT-JT–associated tumors.[30,32] The absence of clinical manifestations of hereditary or syndromic forms of PHPT and any genetic abnormalities within these genes would indicate that the likelihood of a MEN-syndrome, HPT-JT, or FHH was low (i.e., <5%).[30,32,33] First-degree relatives of a PHPT patient with a germline mutation should be identified and offered genetic counseling and appropriate gene testing, and individuals who have inherited the mutation should be offered periodic screening, even if asymptomatic.[30,32,33] First-degree relatives who have not inherited the causative mutation require no further follow-up and may be alleviated of the anxiety associated with the prospect of developing MEN- or HPT-JT–associated tumors.[30,32] For PHPT patients who present at a later age, a detailed family history for PHPT (i.e., FIHP), MEN syndrome, HPT-JT, or FHH should be undertaken, and appropriate clinical evaluations and gene testing should then be undertaken to determine the etiology of the PHPT.[30,32,33] Moreover, it is important to note that greater than 5% of patients with nonfamilial (sporadic) PHPT presenting in the sixth to ninth decade of life with solitary parathyroid adenoma may have a germline mutation involving *CDKN1A, CDKN2B*, or *CDKN2C*, thereby implying a higher risk for developing PHPT in first-degree relatives.[46] Thus, genetic assessment should be undertaken in their first-degree relatives for the presence of the rare variants/mutations of *CDKN1A, CDKN2B,* and *CDKN2C,* and those who have inherited the mutation should have periodic screening to detect the onset of hypercalcemia to facilitate appropriate earlier treatment aimed at preventing the skeletal and renal complications of PHPT.[30,32,46]

Familial Hypocalciuric Hypercalcemia and Disorders of the Calcium-Sensing Receptor

Three hypercalcemic disorders attributed to mutations and/or reduced activity of the CaSR have been reported[54]: FHH (FBH), neonatal severe hyperparathyroidism (NSHPT), and autoimmune hypocalciuric hypercalcemia.[5]

KEY POINTS

- Familial hypocalciuric hypercalcemia (FHH) is a genetically heterogeneous disorder, with FHH type 1 (FHH1), type 2 (FHH2), and type 3 (FHH3) owing to loss-of-function mutations of the calcium-sensing receptor, G protein α11 subunit, and adaptor protein 2 sigma subunit, respectively.

Familial Hypocalciuric Hypercalcemia. FHH is an autosomal dominant disorder characterized by the occurrence of lifelong elevations of serum calcium concentrations with low urinary calcium secretion (mean urinary calcium:creatinine clearance ratio <0.01) and inappropriately normal circulating PTH concentrations in 80% of patients.[5,30] FHH is genetically heterogeneous, with three reported variants, FHH1, FHH2, and FHH3, whose loci were mapped to chromosomes 3q21.1, 19p, and 19q13, respectively.

FHH1 is caused by heterozygous loss-of-function mutations of the CaSR, which signals via Gαq and Gα11.[5] Approximately two-thirds of FHH kindreds will have unique heterozygous mutations of the CaSR, and expression studies of these mutations have demonstrated a loss of CaSR function, whereby there is an increase in the calcium ion–dependent set point for PTH release from the parathyroid cell.

FHH2 is caused by loss-of-function mutations of Gα11, which decrease the sensitivity of cells expressing CaSR, probably by impairing the release of GDP.[5,52] Such Gα11 loss-of-function mutations may occur in less than 5% of FHH patients.

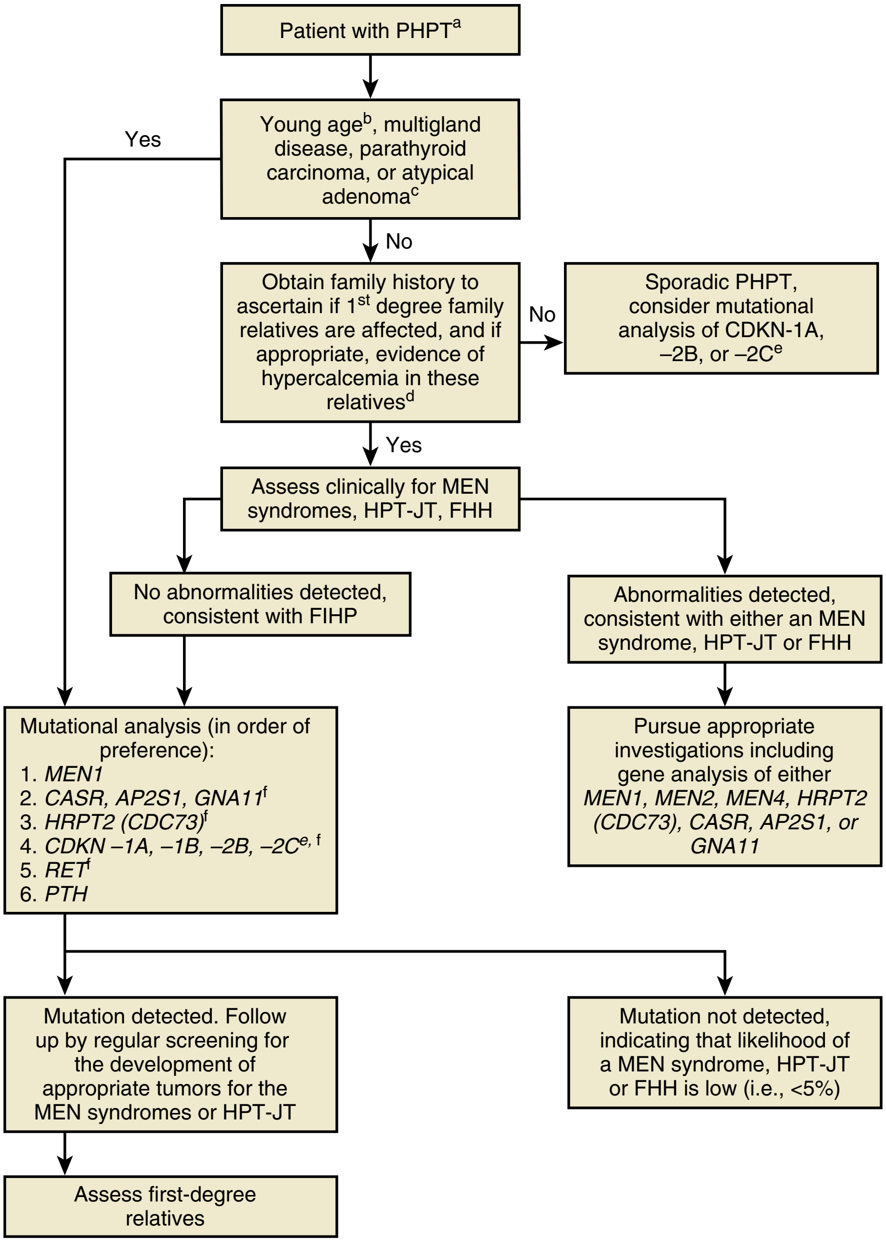
FHH3 is caused by loss-of-function mutations of the adaptor protein 2 (AP-2) sigma subunit (AP2σ).[5,53] AP-2, which is a heterotetramer of α, β, μ, and σ subunits, is a central component of clathrin-coated vesicles (CCVs) and is pivotal in clathrin-mediated endocytosis, that internalizes plasma membrane constituents such as GPCRs. The FHH3-associated AP2σ mutations, which all involve an Arg15 residue that forms key contacts with the dileucine-based motifs of CCV cargo proteins, result in a decreased sensitivity of CaSR-expressing cells to extracellular calcium and reduced CaSR endocytosis. Such AP2σ loss-of-function mutations occur in greater than 5% of FHH patients. FHH1, FHH2, and FHH3 have similar clinical features, and thus studies defining the molecular mechanisms underlying FHH1, FHH2, and FHH3 have helped to distinguish them by genetic analysis, as well as elucidate the CaSR signaling pathway.[5]

Neonatal Severe Primary Hyperparathyroidism. NSHPT occurring in the offspring of consanguineous FHH1 families has been shown to be as a result of homozygous CaSR mutations.[5] However, some patients with sporadic neonatal hyperparathyroidism have been reported to be associated with *de novo* heterozygous CaSR mutations, thereby suggesting that factors other than mutant gene dosage, such as the degree of set-point abnormality, the bony sensitivity to PTH, and the maternal extracellular calcium concentration, may also all play a role in the phenotypic expression of a CaSR mutation in the neonate.[5]

Autoimmune Hypocalciuric Hypercalcemia. Some patients, who have the clinical features of FHH but not *CaSR* mutations, may have AHH.[5,55] Such patients may have multiple clinical autoimmune manifestations, including antithyroid, antigliadin, or antiendomyseal antibodies. These patients were shown to have circulating antibodies to the extracellular domain of the CaSR, and these antibodies stimulated PTH release from dispersed human parathyroid cells *in vitro*, probably by inhibiting activation of the CaSR by extracellular calcium. The effects of treatment with glucocorticoids have been variable, with the hypercalcemia responding in one patient,[55] but not in another.[56] Thus, AHH is a condition of extracellular calcium sensing that should be considered in FHH patients who do not have CaSR mutations.

Other Hereditary Hypercalcemic Disorders

Jansen Disease. Jansen disease (Figs. 52.4 and 52.5) is an autosomal dominant disease that is characterized by abnormal regulation of chondrocyte proliferation and differentiation in the metaphyseal growth plate that leads to the radiographic appearance of severe rickets and adult short stature. During childhood and adolescence, affected patients furthermore present with (usually severe) hypercalcemia and hypophosphatemia, despite normal or undetectable serum levels of PTH or PTHrP, and with hypercalciuria that is associated with nephrocalcinosis; older patients have less severe hypercalcemia, but hypercalciuria persists and contributes to progressive loss of renal function.[57] These abnormalities are caused by mutations in the PTH/PTHrP receptor that lead to constitutive PTH-independent and PTHrP-independent receptor activation. Four different heterozygous mutations affecting three different amino acid residues of the PTH/PTHrP receptor have been identified in the severe form of Jansen disease, and these involve codon 223 (His→Arg), codon 410 (Thr→Pro), and codon 458 (Ile→Arg or Lys). A fifth PTH/PTHrP receptor mutation also affects codon 410 (Thr→Arg) but causes a less severe disease. Expression of the mutant receptors in COS-7 or HEK293 cells resulted in constitutive, ligand-independent accumulation of cAMP, whereas the basal accumulation of inositol phosphates was not measurably increased.[57] Because the PTH/PTHrP receptor is most abundantly expressed in kidney, bone, and the metaphyseal growth plate, these



Patient with PHPT[a]
Young age[b], multigland disease, parathyroid carcinoma, or atypical adenoma[c]
Yes
No
Obtain family history to ascertain if 1st degree family relatives are affected, and if appropriate, evidence of hypercalcemia in these relatives[d]
No
Sporadic PHPT, consider mutational analysis of CDKN-1A, –2B, or –2C[e]
Yes
Assess clinically for MEN syndromes, HPT-JT, FHH
No abnormalities detected, consistent with FIHP
Abnormalities detected, consistent with either an MEN syndrome, HPT-JT or FHH
Mutational analysis (in order of preference):
1. MEN1
2. CASR, AP2S1, GNA11[f]
3. HRPT2 (CDC73)[f]
4. CDKN –1A, –1B, –2B, –2C[e, f]
5. RET[f]
6. PTH
Pursue appropriate investigations including gene analysis of either MEN1, MEN2, MEN4, HRPT2 (CDC73), CASR, AP2S1, or GNA11
Mutation detected. Follow up by regular screening for the development of appropriate tumors for the MEN syndromes or HPT-JT
Mutation not detected, indicating that likelihood of a MEN syndrome, HPT-JT or FHH is low (i.e., <5%)
Assess first-degree relatives

[a] PHPT presenting without manifestations of MEN-associated tumors, or tumors associated with HPT-JT.

[b] Guidelines for MEN1 recommend MEN1 mutational analysis in patients with PHPT occurring before age of 30 years, and ~10% of PHPT patients below the age of 45 years have been reported to have a germline mutation involving the *MEN1, CASR* or *HRPT2* (cdc73) genes.

[c] Atypical parathyroid adenoma may have cysts or fibrous bands.

[d] PHPT may be the first manifestation of MEN1 and HPT-JT in ~90% and ~95% of patients, respectively, with these disorders.

[e] <5% of patients presenting with non-familial (sporadic) and non-syndromic PHPT, due to solitary parathyroid adenomas in the 6th–9th decade of life may have rare variants / mutations of *CDKN1A, CDKN2B,* or *CDKN2C.*

[f] *CASR, AP2S1, GNA11, HRPT2 (CDC73), CDKN1B*, and *RET* mutations are associated with FHH 1, FHH3, FHH2, HPT-JT,MEN4 and MEN2, respectively.

Oxford: Elsevier; 2013:341–363.)

findings provide a likely explanation for the abnormalities observed in mineral homeostasis and growth plate development associated with this disorder. This conclusion is supported further by observations in mice that express the human PTH/PTHrP receptor with the His223Arg mutation under the control of the rat α_1(II) promoter, which resulted in a delayed differentiation of growth plate chondrocytes, abnormal bone elongation, excess trabecular bone mass, and increased bone turnover; bone histomorphometric and biochemical parameters were partially reversed by treatment with an inverse agonist at the mutant PTH/PTHrP receptor.[58]

Williams Syndrome. Williams syndrome is an autosomal dominant disorder characterized by supravalvular aortic stenosis, elfin-like facies, psychomotor retardation, and infantile hypercalcemia. The underlying abnormality causing hypercalcemia, which affects 5% to 50% of patients, remains unknown, but abnormal 1,25-$(OH)_2D$ metabolism or decreased calcitonin production have been implicated, although none have been consistently demonstrated.[59] Studies have demonstrated hemizygosity on chromosome 7q11.23, a region spanning 1.5 to 1.8 million base pairs and containing 26 to 28 genes that include the elastin gene, in over 90% of patients with the classical Williams phenotype. Interestingly, ablation of the elastin gene in mice results in vascular abnormalities similar to those observed in patients with Williams syndrome.[2] However, microdeletions have also been reported to involve the LIM-kinase gene, which is expressed in the central nervous system. Although deletion of the elastin and LIM-kinase genes can explain the respective cardiovascular and neurologic features of Williams syndrome, it seems likely that another, as yet uncharacterized, gene located within this contiguously deleted region is involved in this disorder and could explain the abnormalities of calcium metabolism.[2]

Infantile Hypercalcemia-CYP24A1 and NPT2a Deficiency. Initially referred to as *idiopathic infantile hypercalcemia* (*IIH*), this disorder was shown to be caused by homozygous or compound heterozygous mutations in the gene encoding 24-hydroxylase (CYP24A1), the enzyme that metabolizes and thus inactivates the biologically active 1,25$(OH)_2D$.[2,60] Affected infants develop often severe hypercalcemia and hypercalciuria, leading to nephrocalcinosis and failure to thrive. Besides elevated blood and urinary calcium levels, 1,25$(OH)_2D$ levels are increased, which was shown in one child to dramatically enhance intestinal calcium absorption, thereby suppressing circulating PTH concentrations through two mechanisms, that is, elevated blood calcium and 1,25$(OH)_2D$ concentration.

For several IIH patients, no CYP24A1 mutation could be identified, which led to the discovery of recessive mutations in SLC34A1, the most important sodium-dependent phosphate co-transporter (NPT2a) in the proximal renal tubules.[61] Urinary phosphate-wasting owing to these SLC34A1 mutations increases 1,25-$(OH)_2D$ levels, resulting in symptomatic hypercalcemia. Unlike IHH patients with CYP24A1 mutations, who are treated by reducing vitamin D intake, hypercalcemia in patients with SLC34A1 mutations responds to phosphate Supplementation.

HYPOCALCEMIC DISORDERS

Hypoparathyroidism

Hypoparathyroidism may occur in a syndromic form as part of a pluriglandular autoimmune disorder or as a complex congenital defect (e.g., DiGeorge syndrome). In addition, hypoparathyroidism may develop as a nonsyndromic solitary endocrinopathy, and this has been called *isolated* or *idiopathic hypoparathyroidism*.[1,28] Familial occurrences of isolated hypoparathyroidism with autosomal dominant, autosomal recessive, and X-linked recessive inheritances have been established (Fig. 52.6).

KEY POINTS

- Studies of hypoparathyroidism in humans and mice have revealed that transcriptional cascades involving TBX1, GCM2, GATA3, and SOX3 are likely involved in the development of parathyroid glands from the endoderm of the third pharyngeal pouch. In addition, mutations in the pre-pro portion of parathyroid hormone (PTH) or in the secreted form of PTH can lead to hypocalcemia.

PTH Gene Abnormalities

PTH gene abnormalities affect in most cases the pre-pro portion of PTH; only two mutations have thus far been identified in the secreted

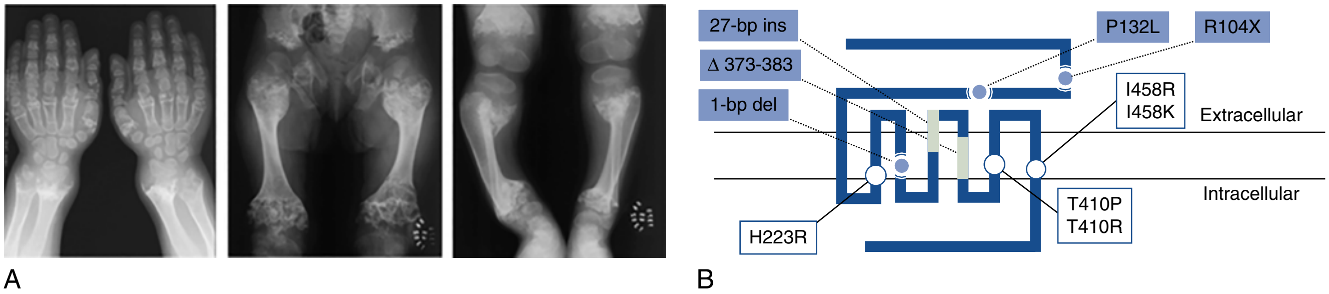

Fig. 52.5 A, Radiographic findings a patient affected by Jansen disease at 6 years of age. B, Schematic representation of the human PTH/PTHrP receptor. The approximate locations of heterozygous missense mutations that lead to constitutive receptor activation in patients with Jansen disease are indicated by *open circles.* Homozygous loss-of-function mutations identified in patients with Blomstrand disease are indicated by *striped boxes* or *gray circles*; the nucleotide exchange in exon M5 of the maternal PTH/ PTHrP receptor allele introduces a novel splice acceptor site that leads to the synthesis of an abnormal receptor protein that lacks portions of the fifth membrane-spanning domain (*stippled box*); for yet unknown reasons, the paternal allele is not expressed in this patient. (From Onuchi L, Ferraz-de-Souza B, Mendonca BB, et al., Potential effects of alendronate on fibroblast growth factor 23 levels and effective control of hypercalciuria in an adult with Jansen's metaphyseal chondrodysplasia. *JCEM.* 2012; 97:1098–1103.)

peptide. The pre-pro missense mutations Met1Cys (which resulted in use of Met7 to initiate translation and a deletion of six amino acids [Met1–Asp6]), Met14Lys, and Cys18Arg[1,28,62] and a donor splice mutation (IVS2 DS, G-C, +1) that resulted in skipping of exon 2 have been reported in patients with isolated hypoparathyroidism. These mutations generally disrupt cleavage of mutant pre-pro PTH to pro PTH, or of mutant pro PTH to the mature PTH, which results in abnormal processing of the mutant peptide in the endoplasmic reticulum (ER), thereby leading to inadequate PTH synthesis or secretion. However, the homozygous mutation Ser32Pro, that is, Ser1Pro of the mature PTH, appears to result in secretion of a PTH molecule, which was detected to be low-normal until mid-adulthood, when it progressively increased to over 100 times the upper limit of normal, that was presumed to be caused by parathyroid hyperplasia, secondary to chronic and appropriate mild undertreatment with calcium and calcitriol and/or chronic mild hyperphosphatemia.[63] In addition, a homozygous PTH mutation affecting a single amino acid residue of the secreted peptide, namely Arg23Cys (Arg56Cys of the pre-pro PTH) is another cause of hypoparathyroidism.[64] The mutation affects the epitope recognized by the detection antibody used in some PTH assays, but not in others, thus leading to descriptions of PTH levels as significantly elevated or undetectable. This further illustrates the complexities in diagnosis of hypoparathyroidism, as well as the value of genetic analysis and knowledge regarding the PTH assay characteristics.

GCM2 Abnormalities

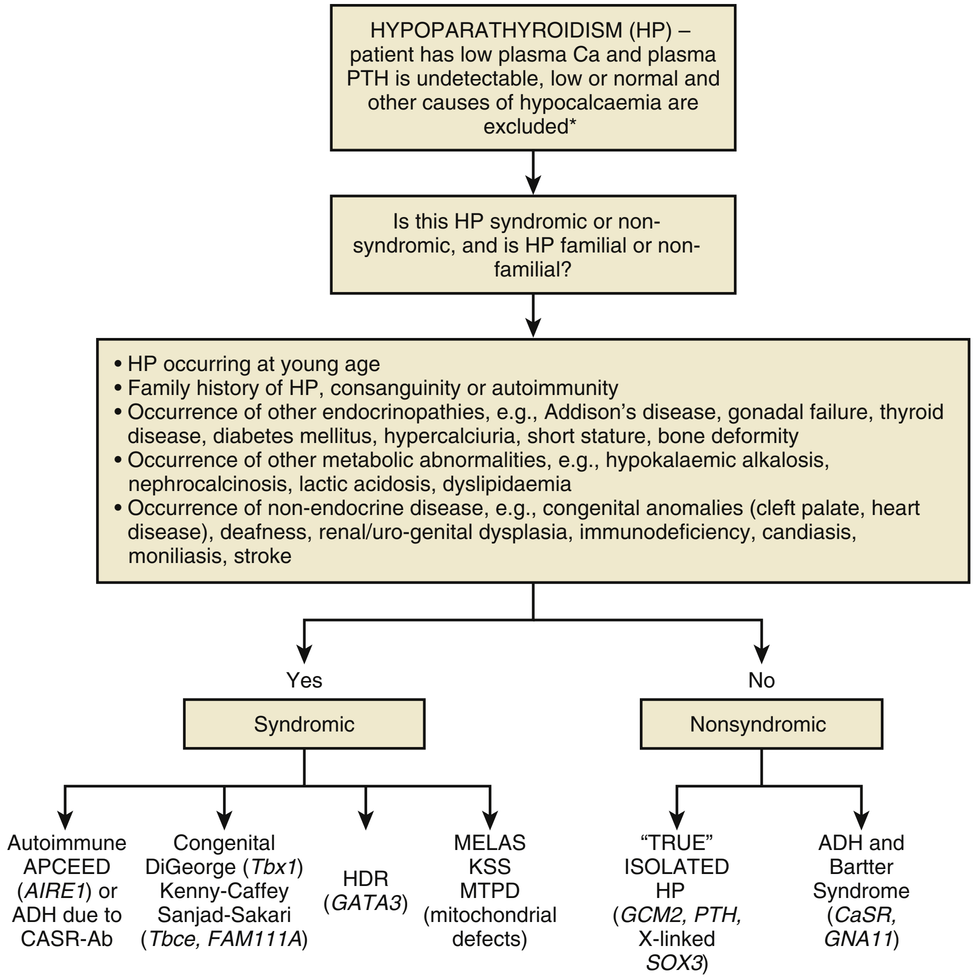
GCM2, also referred to as *GCMB*, is the human homolog of the Drosophila *Gcm* gene and of the mouse *Gcm2* gene. GCM2, which binds to the *PTH* gene 5′ promoter to regulate *PTH* transcription,[1,28] is expressed exclusively in the parathyroid glands, consistent with its role as a specific regulator of parathyroid gland development from the embryonic pharyngeal pouches. Studies of patients with isolated hypoparathyroidism have shown that *GCM2* mutation abnormalities comprising missense and nonsense mutations, and frameshifting and intragenic deletions are associated with autosomal recessive and dominant forms of the disease.[65-68] Studies have shown that these mutations result in a failure of the mutant GCM2 to localize to the nucleus, bind to DNA, or induce transactivation.[66] Moreover, mutant GCMB protein may also be unstable, hyperubiquinated, and degraded via the ubiquitin system.[69]

X-Linked Recessive Hypoparathyroidism

X-linked recessive hypoparathyroidism has been reported in two unrelated kindreds from the United States, and is associated with interstitial deletion-insertions that involve chromosome Xq27.1 downstream of *SOX3* and insertions of predominantly noncoding DNA from chromosome 2p25.3.[70] In this disorder, only males are affected, and they suffer from infantile onset of epilepsy and hypocalcemia, which is caused by an isolated defect in parathyroid gland development. These deletion-insertions are likely to exert a position effect on *SOX3*, expressed in the developing parathyroid glands of mouse embryos, and this indicates a likely role for *SOX3* in the embryonic development of the parathyroid glands.[71]

Pluriglandular Autoimmune Hypoparathyroidism

Hypoparathyroidism may occur in association with candidiasis and autoimmune Addison disease, and the disorder has been referred to as either autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome or autoimmune polyglandular syndrome (APS1) type 1.[1,28] Genetic studies identified *AIRE1* (autoimmune regulator 1), located on chromosome 21q22.3, to be the causative gene for APECED, *AIRE1* encodes a 545–amino acid protein that contains motifs associated with a transcriptional factor and includes two zinc-finger motifs, a proline-rich region, and three LXXLL motifs. Four *AIRE1* mutations are commonly found in APECED families: Arg257Stop in Finnish, German, Swiss, British, and Northern Italian families; Arg139Stop in Sardinian families; Tyr85Cys in Iranian Jewish families; and a 13-bp deletion in exon 8 in British, Dutch, German, and Finnish families. The AIRE1 protein is mainly localized to the nucleus and mediates E3 ubiquitin ligase activity, which is abolished by missense APECED-causing mutations.[72] AIRE1 has been shown to regulate the elimination of organ-specific T-cells in the thymus, and thus APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T-cells and establishing immunologic tolerance.[73] Patients with APS1 may also develop autoantibodies that react with specific autoantigens that are not found in non-APS1 patients; examples of this are autoantibodies to type 1 interferon, which are present in all APS1 patients,[74] and to NACHT leucine-rich-repeat-protein 5 (NALP5), which is a parathyroid-specific autoantibody present in 49% of patients with APS1-associated hypoparathyroidism.[75] NALP proteins are essential components of the inflammasome and activate the innate immune system in different inflammatory and autoimmune disorders, such as vitiligo, which involves NALP1, and



HYPOPARATHYROIDISM (HP) – patient has low plasma Ca and plasma PTH is undetectable, low or normal and other causes of hypocalcaemia are excluded*
Is this HP syndromic or non-syndromic, and is HP familial or non-familial?
• HP occurring at young age
• Family history of HP, consanguinity or autoimmunity
• Occurrence of other endocrinopathies, e.g., Addison's disease, gonadal failure, thyroid disease, diabetes mellitus, hypercalciuria, short stature, bone deformity
• Occurrence of other metabolic abnormalities, e.g., hypokalaemic alkalosis, nephrocalcinosis, lactic acidosis, dyslipidaemia
• Occurrence of non-endocrine disease, e.g., congenital anomalies (cleft palate, heart disease), deafness, renal/uro-genital dysplasia, immunodeficiency, candiasis, moniliasis, stroke

gout, which involves NALP3.[76] The precise role of NALP5 in APS1-associated hypoparathyroidism remains to be elucidated.

DiGeorge Syndrome

Patients with DiGeorge syndrome (DGS) typically suffer from hypoparathyroidism, immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth.[1,28] The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches, with resulting absence or hypoplasia of the parathyroid glands and thymus. Most cases are sporadic, but autosomal dominant inheritance of DGS has been observed, and an association between the syndrome and an unbalanced translocation and deletions involving 22q11.2 have also been reported; this is referred to as DGS type 1 (DGS1). Mapping studies of the DGS1-deleted region on chromosome 22q11.2 defined a 250-kb to 3000-kb critical region that contained approximately 30 genes. However, point mutations in DGS1 patients have only been detected in the *TBX1* gene,[77,78] and *TBX1* is now considered to be the causative gene for DGS1. TBX1 is a DNA-binding transcriptional factor of the T-Box family that is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation.

Some patients may have a late-onset DGS1, and they develop symptomatic hypocalcemia in childhood or during adolescence, with only subtle phenotypic abnormalities. These late-onset DGS1 patients have similar microdeletions in the 22q11 region. It is of interest to note that the age of diagnosis in the families of the three DGS1 patients with inactivating TBX1 mutations ranged from 7 to 46 years, which is in keeping with late-onset DGS1.[77,78]

In some patients, deletions of another locus on chromosome 10p have been observed in association with DGS, and this is referred to as DGS type 2 (DGS2). The *nebulette* (*NEBL*) gene has been reported to be heterozygously deleted in cell lines from two female DGS2 patients, and thus may be the responsible gene.[79]

CHARGE Syndrome

Over 70% of patients with coloboma-heart-anomaly-choanal atresia-retardation-genital-ear anomalies (CHARGE) syndrome have hypocalcemia, likely caused by hypoparathyroidism.[80] CHARGE syndrome may be inherited as an autosomal dominant trait, and in most patients is attributed to *de novo* mutations of the chromodomain helicase DNA-binding protein 7 (CHD7), a transcriptional regulator that binds to enhancer elements in the nucleoplasm, and a minority of patients may have abnormalities involving semaphorin 3E (SEMA3E), which controls cell positioning during embryonic development.[1,28]

Hypoparathyroidism, Deafness, and Renal Anomalies Syndrome

The hypoparathyroidism, deafness, and renal dysplasia (HDR) syndrome is an autosomal dominant disorder.[1,28] Patients may have:

asymptomatic hypocalcemia with undetectable or inappropriately normal serum concentrations of PTH; bilateral, symmetrical, sensorineural deafness involving all frequencies; and renal abnormalities that consist mainly of bilateral renal cysts that compress the glomeruli and tubules, or dysplastic kidneys that may be associated with renal impairment. Genetic studies have established that HDR syndrome is caused by haploinsufficiency of GATA3,[81] which belongs to a family of zinc-finger transcription factors that are involved in vertebrate embryonic development. The majority (>75%) of HDR-associated mutations are predicted to result in truncated forms of the GATA3 protein. GATA3 has two zinc fingers, and the C-terminal finger (ZnF2) binds DNA, while the N-terminal finger (ZnF1) stabilizes this DNA binding and interacts with other zinc finger proteins, such as the Friends of GATA (FOG). HDR-associated mutations involving GATA3 ZnF2 or the adjacent basic amino acids result in a loss of DNA binding, while those involving ZnF1 either lead to a loss of interaction with FOG2 ZnFs or altered DNA binding affinity. Each proband and family will generally have its own unique mutation, and there does not appear to be any correlation with the underlying genetic defect and the phenotypic variation (e.g., the presence or absence of renal abnormalities). Over 90% of patients with two or three of the major clinical features of the HDR syndrome (i.e., hypoparathyroidism, deafness, or renal abnormalities) have a *GATA3* mutation[82]; some patients may also have vaginal and uterine abnormalities. The remaining 10% of HDR patients, who do not have a *GATA3* mutation of the coding region, may harbor mutations in the regulatory sequences flanking the *GATA3* gene, or else they may represent heterogeneity. The phenotypes of HDR patients with *GATA3* mutations appear to be similar to those without *GATA3* mutations.

Mitochondrial Disorders Associated With Hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: Kearns–Sayre syndrome (KSS), MELAS syndrome, and mitochondrial trifunctional protein deficiency syndrome (MTPDS).[1,28] KSS is characterized by progressive external ophthalmoplegia and pigmentary retinopathy before 20 years of age, and it is often associated with heart block or cardiomyopathy. MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both the KSS and MELAS syndromes have been reported to occur with insulin-dependent diabetes mellitus and hypoparathyroidism. A point mutation in the mitochondrial gene tRNA leucine (UUR) has been reported in one patient with the MELAS syndrome who also suffered from hypoparathyroidism and diabetes mellitus. Large deletions, consisting of 6741 and 6903 base pairs and involving more than 38% of the mitochondrial genome, have been reported in other patients who suffered from KSS, hypoparathyroidism, and sensorineural deafness. Rearrangements and duplication of mitochondrial DNA have also been reported in KSS. MTPDS is a disorder of fatty-acid oxidation that is associated with peripheral neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed in one patient with trifunctional protein deficiency. The role of these mitochondrial mutations in the etiology of hypoparathyroidism remains to be further elucidated.

Kenny–Caffey, Sanjad–Sakati, Kirk–Richardson, and Additional Familial Syndromes

Hypoparathyroidism has been reported to occur in over 50% of patients with Kenny–Caffey syndrome (KCS), which is associated with short stature, osteosclerosis and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia.[1,28] There are two types of KCS, with KCS1 and KCS2 being autosomal recessive and dominant traits, respectively, and with KCS2 patients not being affected with mental retardation. In Kirk–Richardson and Sanjad–Sakati syndromes, which are similar and found in patients of consanguineous parents of Middle Eastern origin, hypoparathyroidism is associated with severe growth failure and dysmorphic features. Molecular genetic investigations have identified that mutations in the tubulin-specific chaperone (*TBCE*) gene are associated with KCS1 and Sanjad-Sakati syndromes.[83] *TBCE* encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of α-β tubulin heterodimers (see Fig. 52.2).[83] KCS2 is caused by heterozygous mutations of the family with sequence 111 member A (*FAM111A*) gene, which encodes a chromatin-associated protein involved in DNA replication.

Other familial syndromes in which hypoparathyroidism is a component have been reported, and the causative genetic abnormalities remain to be identified.

Calcium-Sensing Receptor Abnormalities

CaSR abnormalities are associated with three hypocalcemic disorders: autosomal dominant hypocalcemia type 1 (ADH-1), Bartter syndrome type 5 (i.e., ADH with a Bartter-like syndrome), and a form of autoimmune hypoparathyroidism attributed to CaSR autoantibodies.[5]

Autosomal Dominant Hypocalcemia Type 1. ADH1, which is caused by gain-of-function CaSR mutations, is characterized by hypocalcemia that is generally associated with normal serum intact PTH concentrations and hypomagnesemia, and sometimes hypercalciuria.[1,5,28] However, treatment with vitamin D or its active metabolites to correct the hypocalcemia results in marked hypercalciuria, nephrocalcinosis, nephrolithiasis, and renal impairment.

Bartter Syndrome Type 5. Bartter syndrome is a heterozygous group of electrolyte disorders characterized by hypokalemic alkalosis, renal salt wasting that may lead to hypotension, hyperreninemic hyperaldosteronism, increased urinary prostaglandin excretion, and hypercalciuria with nephrocalcinosis.[14] Mutations of ion transporters and channels are associated with Bartter syndrome, and five types are recognized. Thus, type 1 is caused by mutations involving the bumetanide-sensitive sodium-potassium-chloride co-transporter (NKCC2 or SLC12A2); type 2 is caused by mutations of the outwardly rectifying renal potassium channel (ROMK); type 3 is caused by mutations of the voltage-gated chloride channel (CLC-Kb); type 4 is caused by mutations of Barttin, which is a beta subunit that is required for trafficking of CLC-Kb and CLC-Ka (this form is also associated with deafness, as Barttin, CLC-Ka, and CLC-Kb are also expressed in the marginal cells of the scala media of the inner ear that secrete potassium ion-rich endolymph); and type 5 is caused by activating mutations of the CaSR. Patients with Bartter syndrome type 5 have the classical features of the syndrome (i.e., hypokalemic metabolic alkalosis, hyperreninemia, and hyperaldosteronism).[15,84] In addition, they develop hypocalcemia, which may be symptomatic and lead to carp-pedal spasm, and an elevated fractional excretion of calcium that may be associated with nephrocalcinosis.[15,84]

Autoimmune Hypoparathyroidism. Some 20% of patients who had hypoparathyroidism in association with autoimmune hypothyroidism were found to have autoantibodies to the extracellular domain of the CaSR.[5,85] The CaSR autoantibodies persisted for more than 5 years in only 14% of these patients, and a few of them also had features of APS1.

Gα11 Abnormalities and Autosomal Dominant Hypocalcemia Type 2

ADH2, which is caused by gain-of-function Gα11 mutations, has clinical features that are indistinguishable from those of ADH1.[1,5,28,52]

Blomstrand Disease

Blomstrand chondrodysplasia is an autosomal recessive disorder characterized by early lethality, dramatically advanced bone maturation, and accelerated chondrocyte differentiation.[1,28,86] Affected infants are typically born to consanguineous healthy parents (only in one instance did unrelated healthy parents have two affected offspring), show pronounced hyperdensity of the entire skeleton (Fig. 52.7) and markedly advanced ossification, and have long bones that are extremely short and poorly modeled. PTH/PTHrP receptor abnormalities comprising missense (Pro132Leu) and nonsense (Arg104Stop) mutations, a 1-bp deletion and a 27-bp insertion that resulted in a frameshift and a truncated protein, respectively, and a nucleotide exchange that introduced a novel splice acceptor site have been reported (Fig. 52.5). All of these mutations impaired the function of the PTH/PTHrP receptor, thereby indicating that they are the cause of Blomstrand disease. Fetuses with Blomstrand disease are likely to have secondary hyperplasia of the parathyroid glands, presumably attributed to hypocalcemia, and also have abnormal breast development and tooth impaction, highlighting the involvement of the PTH/PTHrP receptor in the normal development of breast and tooth.[87] Moreover, heterozygous PTH/PTHrP receptor mutations leading to haploinsufficiency or functionless receptors also cause the nonsyndromic isolated autosomal dominant disorder of primary failure of tooth eruption.

CONCLUSION

Considerable advances have been made in identifying key proteins that are involved, either directly or indirectly, in the regulation of PTH synthesis or secretion, and in mediating its hormonal actions in the different target tissues. The identification of mutations in several of these proteins furthermore provided a plausible molecular explanation for a variety of familial and sporadic disorders of mineral ion homeostasis and/or bone development. In addition to these advances in further defining the biological role(s) of known proteins, genetic loci and/or candidate genes have been identified for multiple inherited disorders, and these have provided further important insights into the regulation of body calcium.

  Genetic Hypophosphatemia Not Mediated by Elevated FGF23, 917
Possible Future Therapeutic Avenues, 919

The identification of genetic disorders associated with altered phosphate handling has been essential for understanding the mechanisms controlling phosphate homeostasis. Elevated fibroblast growth factor-23 (FGF23) is associated with syndromes manifested by hormonally mediated hypophosphatemia with paradoxically low or normal $1,25(OH)_2$ vitamin D ($1,25(OH)_2D$) and include autosomal dominant hypophosphatemic rickets (ADHR), X-linked hypophosphatemic rickets (XLH), tumor-induced osteomalacia (TIO), and several forms of autosomal recessive hypophosphatemic rickets (ARHR). Other phosphate-wasting diseases result directly in impaired phosphate reabsorption in the nephron. Heritable disorders of hyperphosphatemia and elevated $1,25(OH)_2D$, such as hyperphosphatemic familial tumoral calcinosis (hfTC)/hyperostosis-hyperphosphatemia syndrome (HHS), are associated with reduced FGF23 activity. These collective findings have provided unique insight into the activity of FGF23 on renal phosphate and vitamin D metabolism, as well as the pathophysiology of various disorders. This chapter reviews the clinical manifestations of these disorders, their pathophysiology, current treatment, and strategies for developing new therapies.

REGULATION OF PHOSPHATE HOMEOSTASIS

In contrast to calcium, phosphate is widely distributed in nonosseous tissues, both in inorganic form and as a component of numerous organic molecules ranging from nucleic acids and membrane phospholipids to small phosphoproteins and intermediates of carbohydrate metabolism. These soft-tissue phosphates nevertheless compose only approximately 15% of the total body content, with the remainder of inorganic phosphate being in the mineral phase of bone.

Phosphate in serum exists almost exclusively in association with cations. Unlike calcium, only 12% of phosphate is protein-bound.[1] Also in contrast to calcium, serum phosphate concentrations may vary substantially throughout the day. Carbohydrate ingestion may markedly reduce serum phosphate by moving phosphate from the extracellular to the intracellular space. Moreover, serum phosphate undergoes diurnal variation of as much as 1.5 mg/dL (0.5 mmol/L), with a nadir between 8:00 and 11:00 AM.[2] Hypertriglyceridemia,[3] hypergammaglobulinemia,[4] or mannitol therapy[5] may interfere with measurement of serum phosphate. Serum phosphate concentrations are relatively high in the newborn (5–7 mg/dL)[6] and decrease gradually through childhood to adult levels.

Phosphate is an important substrate for intracellular enzymes involved in glycolysis and respiration that synthesize high-energy phosphate bonds for storage of chemical energy in organophosphate compounds such as adenosine triphosphate (ATP), creatine phosphate, diphosphoglycerate, phosphoenolpyruvate, and others. Severe phosphate depletion leads to inhibition of glycolysis and decreased production of ATP. Adequate extracellular phosphate is required for normal mineralization of bone and cartilage,[7] and chronic hypophosphatemia leads to osteomalacia and, in children, rickets.

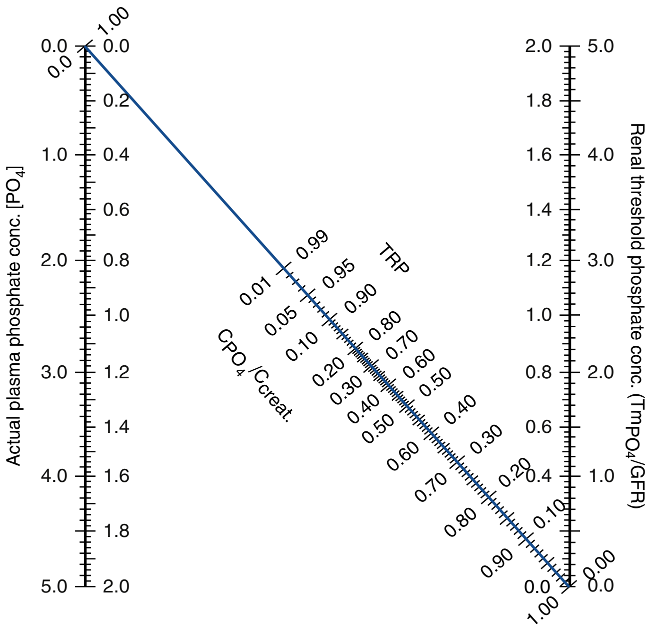
REGULATION OF PHOSPHATE ABSORPTION

The average dietary intake of phosphate—derived largely from dairy products, cereals, and meats—is roughly twice the estimated minimum requirement of 400 mg/day.[8] Absorptive efficiency is high, averaging approximately 70%, and may increase further if the intake of dietary phosphate decreases.[9] Phosphate is avidly absorbed throughout the small intestine, but especially in the jejunum.[10] Sodium-dependent active phosphate absorption is mediated by the NPT2b cotransporters present in the luminal brush-border membranes of enterocytes.[11] Absorption of phosphate is strikingly augmented by $1,25(OH)_2D$ through increased expression of NPT2b.[12]

Phosphate Excretion

Renal tubular reabsorption is the overriding determinant of serum phosphate concentration and is subject to elaborate regulation by a wide variety of hormonal and metabolic factors. As noted earlier, the efficiency of intestinal phosphate absorption is high. Consequently, urinary phosphate excretion is tightly regulated to correlate with enteral phosphate loads.

Eighty percent of phosphate filtered at the glomerulus is reabsorbed by the proximal tubule.[13] Additional phosphate may be reabsorbed in the distal tubule and cortical collecting tubule. Phosphate must



Nomogram for derivation of renal threshold phosphate concentration

Fig. 53.1 Nomogram for calculating the ratio of tubular maximum reabsorption (TMP) to glomerular filtration rate (GFR). Calculations are done from fasting samples obtained in the morning. The urine is collected for 1–2 hours (the time period is not critical). The C_{PO4}/Ccreat = (U_{PO4} × [Creat])/(U_{creat} × [Pi]). To use the nomogram to calculate TMP/GFR, a straight line is passed through the appropriate plasma phosphate concentration and the C C_{PO4}/Ccreat. The line will intersect with the corresponding TMP/GFR value. For SI units, use the inside scales. For metric (mg/dL), use the outside scales. *TRP,* Tubular reabsorption of phosphate. (From Walton RJ, Bijvoet OL. Nomogram for derivation of renal threshold phosphate concentration. *Lancet.* 1975;2:309–310.)

be actively transported across the luminal brush-border membrane against a steep electrochemical gradient. Consistent with this, renal phosphate transport requires luminal sodium ions and is blocked by inhibitors of Na^+/K^+-ATPase.[14]

The two primary transport proteins responsible for phosphate reabsorption in the kidney are the type II sodium-phosphate cotransporters NPT2a and NPT2c, expressed in the apical membrane of the proximal tubule. Ablation of the *Npt2a* gene in the mouse results in a decrease in proximal tubular sodium phosphate cotransport, hypophosphatemia, and loss of regulation of phosphate reabsorption by both parathyroid hormone (PTH) and dietary phosphate.[15,16,17] Ablation of NPT2c in mice does not result in a phosphate phenotype.[18] However, mutations in the gene coding NPT2c, *SLC34A3*, result in hereditary hypophosphatemic rickets with hypercalciuria (HHRH), indicating that this transporter plays an important role in maintaining phosphate homeostasis in humans.

Measurement of Renal Phosphate Transport. For clinical purposes, a useful way of assessing a patient's ability to reabsorb phosphate is to calculate the tubular maximum reabsorption (TMP) of phosphate divided by the glomerular filtration rate (GFR). A simple nomogram has been developed by Walton and Bijvoet[19] (Fig. 53.1), though it does not encompass the upper end of the normal range of serum phosphate or of TMP/GFR in young children.

Regulation of Phosphate Reabsorption

Parathyroid Hormone. PTH has a major effect on serum phosphate. The clinical relevance of this effect is demonstrated in patients with hyperparathyroidism, who develop phosphaturia and hypophosphatemia, as well as those with hypoparathyroidism, who have increased phosphate reabsorption and hyperphosphatemia. PTH rapidly (15–60 minutes) reduces the number of NPT2a cotransporters on the apical surface of the cells in the renal proximal tubule. Despite the fact that PTH clearly has a major effect on phosphate homeostasis, the primary role of PTH is to regulate serum calcium and not phosphate homeostasis, as PTH secretion is regulated more by serum calcium than serum phosphate.

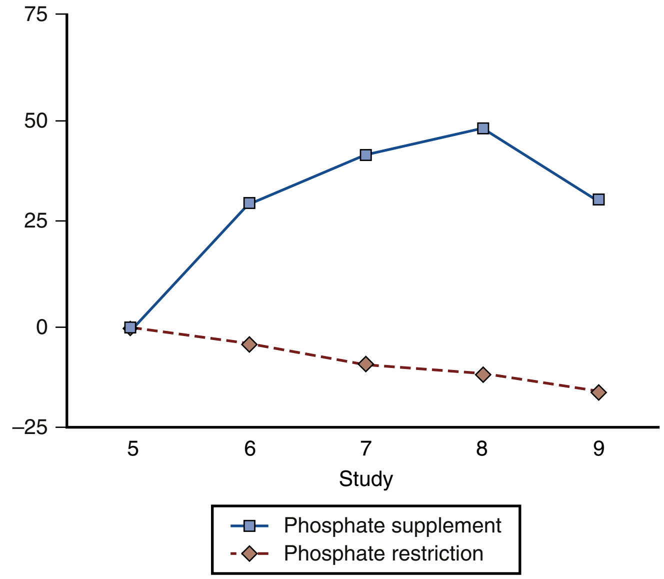


Fig. 53.2 Fibroblast growth factor-23 (FGF23) levels in response to diet. Percent change in FGF23 during the intervention period (♦, phosphate depletion intervention as measured with the intact FGF23 assay; ■, phosphate loading intervention as measured with the intact FGF23 assay). The intervention, either dietary phosphate depletion or loading, was started after the day 5 samples were collected. Values are presented as mean ± standard error. (Data from Burnett SM, Gunawardene SC, Bringhurst FR, et al. Regulation of C-terminal and intact FGF-23 by dietary phosphate in men and women. *J Bone Miner Res.* 2006;21:1187–1196.)

Fibroblast Growth Factor-23

FGF23, the gene identified as causative for autosomal dominant hypophosphatemic rickets and some forms of hfTC, does not appear to play a role in the rapid changes in phosphate reabsorption that occur following acute changes in intestinal phosphate content.[20] However, there is substantial evidence that FGF23 plays a role in maintenance of phosphate homeostasis over the course of days.

Fibroblast Growth Factor-23 Activity

FGF23 has similar functions as PTH to reduce renal phosphate reabsorption but has opposite effects on $1,25(OH)_2D$ production. FGF23 delivery leads to renal phosphate wasting through the downregulation of both NPT2a and NPT2c.[21] Under normal circumstances, hypophosphatemia is a strong positive stimulator for increasing serum $1,25(OH)_2D$ production. However, in mice, the expression of the $1\alpha(OH)$ase enzyme and the catabolic 24(OH)ase are reduced and elevated, respectively, when the animals are exposed to FGF23.[22] Thus, the effects of FGF23 on the renal vitamin D metabolic enzymes are responsible for the reductions in $1,25(OH)_2D$ seen in the setting of hypophosphatemia in ADHR, XLH, TIO, and ARHR patients.

Regulation of Fibroblast Growth Factor-23 Production

In humans, dietary phosphate supplementation increased FGF23, whereas phosphate restriction and the addition of phosphate binders suppressed serum FGF23 (Fig. 53.2),[23] indicating that FGF23 plays a role in maintaining phosphate homeostasis. In animal studies, the FGF23 response to serum phosphate appears more dramatic than in the human studies. Mice given high- and low-phosphate diets have increased and decreased *FGF23* gene expression, respectively, with corresponding changes in plasma FGF23 levels.[24]

Vitamin D has important regulatory effects on FGF23 *in vivo*. In mice, injections of 20 to 200 ng $1,25(OH)_2D$ led to dose-dependent increases in serum FGF23 concentrations.[22] These changes in FGF23 occurred before detectable changes in serum phosphate, indicating that FGF23 is probably directly regulated by vitamin D. Physiologically, this feedback mechanism is consistent with the role of FGF23 in vitamin D metabolism, in that FGF23 has been shown to downregulate the 1α(OH)ase mRNA.[21,22] Thus, as $1,25(OH)_2D$ is elevated in the blood as a product of 1α(OH)ase activity, vitamin D would then increase FGF23 production, which completes the negative feedback loop and downregulates 1α(OH)ase.

Enzyme-Linked Immunosorbent Assays Specific for Fibroblast Growth Factor-23. FGF23 can be measured in the bloodstream via several assays. One widely used assay is a C-terminal FGF23 enzyme-linked immunosorbent assay (ELISA), with both the capture and detection antibodies binding C-terminal to the $FGF23_{176}RXXR_{179}/S$ cleavage site.[25] This assay thus recognizes full-length FGF23 as well as C-terminal fragments that arise through proteolytic processing. The normal mean for this assay is 55 ± 50 reference units (RU)/mL, and the upper limit of normal is 150 RU/mL. Plasma FGF23 is detectable in normal individuals.[25] The mean C-terminal FGF23 value was greater than 10-fold elevated in TIO patients, falling rapidly after surgical resection. Importantly, most XLH patients (13 out of 21) had elevated FGF23 compared to controls,[25] and in those with "normal" FGF23, these levels may be considered "inappropriately normal" in the setting of hypophosphatemia.

There are multiple intact FGF23 assays using monoclonal monoclonal antibodies that bind to either side of the protein's $_{176}RXXR_{179}/S_{180}$ subtilisin-like proprotein convertase (SPC) cleavage site to recognize only the full-length protein.[26] In normal individuals, the Kainos intact assay has a mean circulating concentration of 29 pg/mL. The published upper limit of normal is 54 pg/mL.[26] The results of these two assays generally have good agreement regarding the relative elevations of FGF23 concentrations in XLH and in TIO patients. However, in diseases such as hfTC, and during iron deficiency, the intact and C-terminal ELISAs do not correspond, which is reflective of the underlying disease mechanisms. Based upon limited data from two TIO patients undergoing resection, the Kainos intact assay was used to determine that the half-life of FGF23 is between 20 and 50 minutes.[27] Additional intact FGF23 assays have been developed, but normal ranges with each intact assay may differ. The intact FGF23 level using the Kainos assay is generally similar when measuring plasma or serum samples. However, serum C-terminal FGF23 or intact FGF23 levels measured using assays from Immutopics are systematically much lower than those measured from plasma.[28] Thus, appropriate ranges need to account for the specific assay and manufacturer and the type of blood sample being measured.

KEY POINTS

- Phosphate metabolism is regulated at the level of the kidney, bone, and intestine and involves the hormones $1,25(OH)_2$ vitamin D ($1,25(OH)_2D$), parathyroid hormone, and fibroblast growth factor-23 (FGF23).
- FGF23 is produced in osteocytes and acts in the kidney though its coreceptor alpha-Klotho.
- FGF23 acts to down regulate $1,25(OH)_2D$ production and directly inhibit phosphate reabsorption in the kidney through internalization of proximal tuble sodium-phopshate cotransport proteins.
- Enzyme-linked immunosorbent assays have been developed for the intact, bioactive form of FGF23, as well as an assay that recognizes the C-terminal portions of FGF23.

FIBROBLAST GROWTH FACTOR-23–ASSOCIATED SYNDROMES

FGF23-associated syndromes, summarized in Table 53.1, which are discussed further as follows.

Disorders Associated with Increased FGF23 Bioactivity

Autosomal Dominant Hypophosphatemic Rickets. ADHR is a rare disorder characterized by low serum phosphate concentrations due to decreased TMP/GFR and inappropriately low or normal circulating vitamin D concentrations.[29] A large kindred demonstrated the wide phenotypic variability of ADHR. In contrast to the other genetic renal phosphate-wasting disorders, ADHR displays incomplete penetrance and variable age of onset. Some patients presented during childhood with phosphate wasting, rickets, and lower-extremity deformity similar to the classic presentation of XLH. Other individuals had grown normally without rickets but presented during adolescence or adulthood with new-onset hypophosphatemia. These individuals had bone pain, weakness, and insufficiency fractures.[29] The patients with adult-onset ADHR had clinical presentations essentially identical in clinical severity to patients with TIO. To date, most patients described with delayed onset of clinically evident disease are female. In addition, we found unaffected individuals with the ADHR mutation and patients who were treated for hypophosphatemia and rickets but later lost the phosphate-wasting defect.[29]

FGF23 was identified from genome-wide linkage studies in this and other kindreds and using exon prediction programs using genomic DNA sequence from the Human Genome Project.[30] The *FGF23* gene is composed of three coding exons and contains an open reading frame of 251 residues.[30] The tissue with the highest FGF23 expression is bone, where FGF23 mRNA is observed in osteoblasts, osteocytes, flattened bone-lining cells, and osteoprogenitor cells.[31] Quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) showed that FGF23 mRNA was most highly expressed in long bone, followed by thymus, brain, and heart.[32]

Western blot analysis demonstrated that wild-type FGF23 is secreted as a full-length 32-kD protein, as well as cleavage products of 20 kD (N-terminal) and 12 kD (C-terminal).[32-34] Cleavage of FGF23 occurs within a SPC proteolytic site ($_{176}RXXR_{179}/S_{180}$) that separates the conserved FGF-like N-terminal domain from the variable C-terminal tail (Fig. 53.3).

The ADHR mutations replace arginine (R) residues at FGF23 positions 176 or 179 with glutamine (Q) or tryptophan (W) within the SPC cleavage site, $_{176}RXXR_{179}/S_{180}$ (Table 53.2 and see Fig. 53.3).[30,33-36] The SPCs are a family of serine proteases that process a wide variety of proteins, including neuropeptides, peptide hormones, growth factors, membrane-bound receptors, blood coagulation factors, and plasma proteins.[37] SPC substrates are cleaved C-terminal to the basic motif K7R-X,,-K7R, where X_n = 2, 4, or 6 residues of any amino acid.[38,39] The SPCs, such as the furin protease, are largely expressed in the trans-Golgi network and possess similar, but not exact, substrate specificities.

Following insertion of these mutations into wild-type FGF23, FGF23 secreted from mammalian cells was primarily produced as the full-length (32 kD) active polypeptide, as opposed to the cleavage products observed for wild-type FGF23 expression.[33] Peptide sequencing demonstrated that the 32-kD FGF23 form corresponded to full-length FGF23 after cleavage of the signal peptide (residues 25 to 251) and that the 12-kD isoform was the C-terminal portion of FGF23 downstream from the SPC cleavage site after R179 (residues 180–251) (see Fig. 53.3).[34] These studies show that the RXXR motif in FGF23 is central to its intracellular processing.

TABLE 53.1 Heritable and Acquired Disorders Involving Fibroblast Growth Factor-23 (FGF23)

Disorder	Gene Mutated	Mutation Consequence	Relationship to FGF23	Effect on Serum Phosphate	Effect on Serum 1,25D	Intact ELISA (FGF23)	C-Terminal ELISA (FGF23)	Respective Animal Models

Fig. 53.3 Model of fibroblast growth factor-23 (FGF23) protein domains and effect of the autosomal dominant hypophosphatemic rickets (ADHR) mutations. FGF23 has a 24-residue signal peptide followed by residues 25–179 that comprise the conserved N-terminal fibroblast growth factor (FGF)-like domain. The subtilisin-like proprotein convertase (SPC)-like site is interrupted by the ADHR mutations at R_{176} and R_{179} and divides the FGF-like domain from the variable C-terminal tail region. FGF23 undergoes glycosylation at three regions (denoted *), with T_{178} most likely being the glycosylated residue that protects the mature protein from SPC proteolysis between R_{179} and S_{180}, and is therefore critical for maintaining intact, active FGF23. The FAM20C phosphorylation site at S180 blocks GALNT3-mediated glycosylation of FGF23, leading to destabilization of intact bioactive FGF23.

ADHR, Autosomal dominant hypophosphatemic rickets; *FTC,* familial tumoral calcinosis.

Cleavage of FGF23 at the RXXR motif appears to be inactivating. In this regard, when full-length FGF23 or N-terminal (residues 25–179) and C-terminal (residues 180 –251) fragments were injected into rodents, only the full-length protein lowered circulating phosphate concentrations.[34] Because the full-length form of FGF23 induces hypophosphatemia, it is likely that the ADHR mutations increase the biological activity of FGF23 by stabilizing the full-length form and increasing its concentrations in the serum. Indeed, severely affected ADHR patients have increased circulating levels of FGF23.[40] However, until recently it was unclear why ADHR patients were not able to simply reduce *FGF23* gene expression. The answer to this dilemma came from an unexpected connection between iron and FGF23.

Iron and Fibroblast Growth Factor-23 Interactions. Studies in ADHR kindreds demonstrated that disease status varied with FGF23 concentrations.[40] Subjects with ADHR mutations that did not manifest hypophosphatemia had normal FGF23 concentrations, while hypophosphatemic patients had elevated FGF23 concentrations. Cross-sectional and longitudinal studies demonstrated an inverse correlation between serum phosphate and FGF23 concentrations in ADHR patients, but not controls. In ADHR patients, low iron concentrations resulted in elevations in both total (intact and fragments as measured by the C-terminal assay) and intact FGF23 concentrations. However, in control individuals, low iron concentrations were also associated with elevated total FGF23 concentrations measured by the C-terminal assay, while intact FGF23 concentrations were normal.[41]

Studies in the ADHR mouse provide a detailed mechanism for the above observations. When placed on an iron-deficient diet, both control and R176Q-Fgf23 knockin mice (the animal model of ADHR) had marked elevations in bone Fgf23 mRNA. Wild-type mice on the low-iron diet maintained normal serum intact Fgf23 and phosphate concentrations but displayed elevations in serum C-terminal Fgf23 levels. In contrast, the ADHR mice receiving the low-iron diet had elevated intact, biologically active Fgf23 as well as C-terminal Fgf23, which resulted in hypophosphatemic osteomalacia.[42] Additionally, *in vitro* studies using the osteoblastic cell line UMR-106 demonstrated that iron chelation with 25 or 50 uM deferoxamine increased Fgf23 mRNA 12- and 20-fold, respectively.[42] The mechanism is mediated by increased expression of hypoxia inducible factor 1α.[42] Additional studies[43] demonstrate that hypoxia can also increase FGF23 production. In this regard, UMR-106 cells grown under reduced oxygen tension, but normal iron concentrations, increase FGF23 mRNA over 3-fold by 24 hours. Furthermore, normal Sprague-Dawley rats exposed to hypoxia for 2 weeks resulted in over 6-fold increase in C-terminal Fgf23 compared with control rats at normal oxygen tension, with no change in intact Fgf23 or serum phosphate, supporting the concept that hypoxia increases Fgf23 expression, but normal individuals are able to cleave FGF23 to prevent hypophosphatemia. Interestingly, studies done in neonatal mice whose mothers were fed an iron-deficient diet demonstrate increased intact FGF23 and hypophosphatemia in wild-type mice, although not to the same extent observed in ADHR mice.[43] These findings raise the possibility that iron deficiency during pregnancy could have negative effects on the FGF23/phosphate/calcitriol/bone axis in normal humans. Additionally, inflammation that causes a functional iron deficiency,[44] and other regulators of iron handling, such as erythropoietin,[45] also increase circulating FGF23. Although, without an ADHR mutation, acute intact FGF23 increases, but with longer exposure the major species detected in plasma from normal individuals and rodents are C-terminal fragments.[44]

Taken together, studies in human subjects and in animal models demonstrate that iron deficiency and hypoxia increase expression of FGF23 mRNA and protein in bone. In individuals without an FGF23 mutation, the excess FGF23 protein is cleaved into inactive fragments (inactive with respect to phosphate and calcitriol homeostasis). However, patients and mice with ADHR mutations are unable to cleave the excess mutant FGF23 and manifest elevated intact FGF23 concentrations resulting in hypophosphatemia and inappropriately normal calcitriol concentrations. Thus, disease status in ADHR is a product of gene–environment interactions in which the combined presence of an FGF23 mutation and iron deficiency results in the biochemical and phenotypic manifestations of ADHR.

To close the loop on this pathophysiology, we conducted an open-label clinical trial treating symptomatic ADHR patients and individuals at risk for becoming symptomatic based on serum iron levels, starting with a daily dose of 65 mg of oral iron (ferrous sulfate 325 mg tablets). Doses were adjusted according to a prespecified algorithm. Oral iron was chosen in light of studies indicating that intravenous iron could trigger transient acute increased intact FGF23 and hypophosphatemia in normal iron-deficient individuals.[46] By the end of the 12-month trial, all subjects were normophosphatemic, with normal C-terminal and intact FGF23 concentrations, and those that were treated with calcitriol and phosphate therapy were able to discontinue these while maintaining normophosphatemia.[47] Thus, treatment with oral iron to replete iron stores was able to normalize intact FGF23 and serum phosphate in patients with ADHR.

KEY POINTS

- Fibroblast growth factor-23 (FGF23) gene expression is increased in the setting of iron deficiency.
- Cleavage of FGF23 before secretion is a regulated step, and during iron deficiency FGF23 cleavage maintains normal intact FGF23 and phosphate despite the elevated gene expression.
- Some types of intravenous iron can paradoxically acutely increase the intact FGF23 transiently for weeks after dosing in the setting of iron deficiency. This is thought to be caused by a secondary effect of the carbohydrate moiety of iron infusions to impair FGF23 cleavage combined with the setting of iron deficiency–induced elevated *FGF23* gene expression.
- Autosomal dominant hypophosphatemic rickets (ADHR) is caused by mutations that impair the cleavage of FGF23, resulting in increased FGF23 concentrations that appear to manifest primarily during iron deficiency.
- Oral iron repletion to normal iron stores can normalize the FGF23 and phosphate levels in ADHR.

Tumor-Induced Osteomalacia. TIO is an acquired disorder of renal phosphate wasting that is associated with tumors. Patients with TIO present with hypophosphatemia with inappropriately suppressed $1,25(OH)_2D$ concentrations and elevated alkaline phosphatase levels.[48] Clinical symptoms include gradual onset of muscle weakness, fatigue, and bone pain, especially from ankles, legs, hips, and back.[48,49] Osteomalacia is observed in bone biopsies. Insufficiency fractures are common, and proximal muscle weakness can become severe enough for patients to require a wheelchair or become bedbound.[48] FGF23 mRNA and protein have been demonstrated to be highly expressed in these tumors, and plasma levels are usually correspondingly elevated.[25,50,51]

X-Linked Hypophosphatemic Rickets (OMIM No. 307800). XLH is an X-linked dominant disorder and the most common form of heritable rickets. XLH is fully penetrant, with variable severity. XLH patients present with laboratory findings that include hypophosphatemia with normocalcemia and inappropriately normal or low $1,25(OH)_2D$ concentrations.[52] Skeletal defects include lower-extremity deformities from rickets, short stature, dental abscesses, bone pain, osteomalacia, fracture, enthesopathy (calcification of the tendons and ligaments), and early-onset osteoarthritis. XLH is caused by inactivating mutations in *PHEX* (***p****hosphate-regulating gene with* ***h****omologies to* ***e****ndopeptidases on the* ***X*** *chromosome*).[53] Based upon sequence homology, PHEX encodes a protein that is a member of the M13 family of membrane-bound metalloproteases. Other members of this enzyme class include neutral endopeptidase and endothelin-converting enzymes 1 and 2.[53,54] This family is known to cleave small peptides. Over 300 inactivating *PHEX* mutations have been described in XLH patients, including genomic variations causing missense, nonsense, frameshift, and splicing changes (see PHEX Locus database: www.phexdb.mcgill.ca). PHEX shows the highest expression in bone cells such as osteoblasts, osteocytes, and odontoblasts in teeth, as well as lower expression in the parathyroid glands, lung, brain, and skeletal muscle, but no expression in kidney.[55]

A valuable tool for the study of the pathophysiology of XLH has been the *Hyp* mouse, which has 3′ deletion in the *Phex* gene from intron 15 through the 3′ untranslated region and does not make a stable Phex transcript.[55] This rodent model parallels the XLH biochemical phenotype, as well as having growth retardation and bone mineralization defects.[56]

X-Linked Hypophosphatemic Rickets and Fibroblast Growth Factor-23. Several reports have established that FGF23 is elevated in most XLH patients.[25,26] Quantitative real-time RT-PCR indicates that FGF23 mRNA in bone from *Hyp* mice is elevated compared with control mice,[32] and serum concentrations of FGF23 are up to 10-fold higher in *Hyp* mice compared with normal mice.[57] This finding indicates that there is a cellular connection between inactive PHEX mutants (or lack of Phex expression in *Hyp* mice) and the upregulation of FGF23 mRNA in bone cells resulting in overproduction and secretion of FGF23 by skeletal cells. Although the interactions between FGF23 and PHEX are most likely indirect, the encoded proteins are coexpressed in osteoblasts and osteocytes.[31,55] Although one report[58] provides evidence that PHEX can cleave osteopontin, its physiologically relevant substrate and the mechanisms for phosphate sensing are unknown. A further complication is that, not only are FGF23 mRNA and protein expression increased, but the ratio of intact FGF23 to total FGF23, as measured by the C-terminal assay, is increased in both Hyp mice[59] and XLH patients.[60] Although PHEX does not cleave FGF23, absence of PHEX may influence not only FGF23 expression, but reduce cleavage of intact, biologically active FGF23.

Interestingly, despite persistent hypophosphatemia during therapy with active vitamin D and phosphate salts, serum FGF23 concentrations generally rise in response to therapy.[61] To explore this phenomenon further, Ichikawa et al.[59] crossed mice with *Phex* mutations with *Galnt3*-null mice. GALNT3/Galnt3 O-glycosylates FGF23, protecting the FGF23 protein from degradation, and GALNT3 mutations lead to tumoral calcinosis (TC).[62] Humans and mice with these mutations have markedly decreased intact, biologically active FGF23 and manifest hyperphosphatemia and soft tissue calcificaitons (see later). Hyp mice displayed hypophosphatemia and elevated total (intact plus fragments) and intact FGF23 concentrations, whereas *Galnt3*-null mice were hyperphosphatemic with low intact FGF23 concentrations, but had high FGF23 mRNA expression and high total FGF23 concentrations (almost all inactive fragments). In the absence of altered phosphate responsiveness, FGF23 mRNA expression in the double mutant would be expected to be similar to the Hyp. However, the Hyp/Galnt3 double mutant remained hypophosphatemic with serum phosphate concentrations slightly, but significantly, higher than Hyp, and with markedly upregulated FGF23 gene expression even higher than the Hyp mouse (up to 24-fold higher than the 12-week-old Hyp mice, and 113-fold higher than control mice), with corresponding total FGF23 levels.[59] This study further supports the concept that PHEX deficiency lowers the regulated serum phosphate set point.

KEY POINTS

- X-linked hypophosphatemic rickets (XLH) is a lifelong condition resulting in chronic hypophosphatemia due to fibroblast growth factor-23 excess.
- Children with XLH generally present with features of rickets and poor growth.
- Adults with XLH manifest with bone pain, pseudofractures, and progressive osteoarthritis and enthesopathy, impairing mobility and quality of life.
- Dental complications are common in both children and adults.

Clinical Treatment of X-Linked Hypophosphatemic Rickets. Current treatment options of XLH include "conventional therapy" using a combination of phosphate salts and active vitamin D or monotherapy with burosumab.

Conventional Therapy. For several decades, the conventional therapy for XLH, ADHR, and TIO has involved administration of oral phosphate salts in combination with high-dose active forms of vitamin D (using calcitriol or alfacalcidol).[52] This regimen ameliorates much of the metabolic bone disease, but it does not directly "cure" the disorder, in that it does not reverse the underlying molecular defects in kidney and in bone. Therapy is labor-intensive, requiring multiple doses per day to be effective, as well as frequent laboratory monitoring for safety. Unfortunately, the conventional therapy has often been mistaken as taking nutritional "supplements," leading insurance companies to often deny coverage and patients and providers to overlook the real risks of important side effects of conventional therapy.

In fact, nutritional vitamin D supplementation has long been known to be ineffective at treating XLH, leading to one of its old names, as a "vitamin D–resistant rickets." In reality, XLH has nothing to do with resistance to vitamin D at its receptor. Thus, this name was not mechanistically accurate. In XLH, rickets and osteomalacia persist even despite very high doses of vitamin D, which are complicated by risk for vitamin D toxicity. Attempts to treat with phosphate salts alone, however, suffered from lack of effect to heal the rickets or osteomalacia, and are accompanied by very high risk for hyperparathyroidism. Eventually, multiple studies demonstrated that the combination of active forms of vitamin D (calcitriol, alfacacidol) with phosphate salts is necessary for improving the rickets and osteomalacia. However, medical therapy requires an ability to carefully monitor labs for safety. The goals of conventional therapy are not to normalize serum phosphate. In fact, overly aggressive attempts to normalize phosphate with conventional therapy may be associated with complication of therapy.[52]

The objectives of therapy in children are to correct or prevent deformity from rickets, promote growth, and lessen bone pain. In some cases, marked improvement in lower-extremity deformity is noted with medical therapy. Thus, surgical approaches to correcting lower-extremity deformities (using osteotomies or guided growth procedures) can often be delayed for a period of time in young children to see the magnitude of benefit from medical therapy alone. However, the response to conventional therapy is quite variable, and the need for corrective surgery remains quite common. Growth remains impaired, and the mean adult height is less than –2.5 standard deviation scores.[63] Most affected children probably should be treated if a system exists to safely administer and monitor therapy, including frequent laboratory assessments (usually every 3–4 months).

The indications for treatment of adult patients are more controversial.[52] Historically, most children have stopped treatment at the end of their growth, due to the complex balance of risks versus benefits. Some adults do well for a period of time without pain or fractures, while others develop these symptoms, which may be mild or severe and develop early or later in adulthood. Unfortunately, after stopping treatment at the end of growth, patients may wrongly assume that symptoms such as pain or fracture are due to something else, leading to great delays in reestablishing care and treatment. Additional delays may be caused by providers assuming that XLH is a disease of childhood, when in fact adults bear a large burden of disease. In a burden of disease study of 232 adults, 97% reported bone pain, joint pain, and stiffness, and 44 % had a history of fracture.[64] Of these adult respondents, 86% had abnormal gait (likely due to a combination of the residual effect of childhood deformities, as well as of their bone pain, osteoarthritis, and enthesopathy). The adult features of XLH are dominated by bone pain, pseudofracture, osteoarthritis, and enthesopathy. However, there are no data to suggest that conventional therapy for XLH prevents enthesopathy (calcifications of tendons and ligaments)[65] or osteoarthritis. XLH patients frequently complain of bone pain,[64] presumably due to osteomalacia. However, pseudofractures are common in moderately to severely affected adult XLH patients and are often unrecognized as a source of bone pain; thus, radiographs should be routine in evaluating patients with bone pain.[66] Because pseudofractures are often painful, may lead to complete fracture, and may be improved by treatment, medical therapy is generally recommended for patients with pseudofractures. Patients with bone pain, even without pseudofracture, may benefit from a trial of therapy. Additionally, it is advisable to treat patients who have nonunion after fractures or osteotomies, or after undergoing other orthopedic procedures, to help with bone healing.[52]

Once the decision is made to initiate conventional therapy, it is best to start at a low dose of calcitriol and phosphate (to avoid diarrhea from phosphate) and gradually increase therapy to target doses over several weeks for tolerability. It is important not to treat XLH with phosphate alone. Guidelines have recommended phosphate salts in doses ranging from 20 to 60 mg/kg daily be combined with either calcitriol 20 to 40 ng/kg daily or alfacalcidol 30 to 50 ng/kg daily. Phosphate doses usually need to be divided across four doses in a day, while calcitriol is usually given twice a day. Some clinicians have recommended administering phosphate over five doses per day; however, we do not ask patients to wake up to take medication at night, for the following reasons: (1) serum phosphate concentrations tend to rise at night in XLH patients, (2) there is an exaggerated nocturnal rise in PTH concentrations in XLH patients, and (3) it is very difficult for patients to wake up to take medication every night for a chronic condition.[67] Doses are individualized based on a combination of factors to optimize and balance tolerability, risks, and benefits.[52] Some patients may require higher doses for a period of time to improve bone healing. This has to be balanced with noting that higher doses may be associated with more side effects, including nephrocalcinosis and hyperparathyroidism. In addition, calcitriol and phosphate intake stimulate FGF23 expression, further increasing plasma FGF23 levels even in XLH patients.[68] There are currently no data as to whether it is clinically useful to monitor FGF23 concentrations during conventional therapy. However, increases in FGF23 concentrations are a possible unwanted side effect of standard therapy as well as any therapy that increases phosphate and/or calcitriol concentrations without correcting the hypothesized osteocyte phosphate set-point defect.

Careful laboratory monitoring is required when employing conventional therapy. Serum calcium, phosphorus, and creatinine levels, as well as urine calcium and creatinine concentrations, should be routinely monitored for safety, on a monthly basis during dose escalation and then every 3 to 4 months afterward. Alkaline phosphatase can be monitored as a sign of healing of rickets or osteomalacia. PTH should also be monitored every 6 months. The doses of calcitriol and phosphate are adjusted based on the laboratory results, but not necessarily targeting normal serum phosphate. Administration of phosphate leads to secondary hyperparathyroidism, while administration of active vitamin D can lead to hypercalciuria and hypercalcemia. Hence, a patient on conventional therapy can develop hypercalciuria as a consequence of either too much $1,25(OH)_2D$ or too little phosphate. Hypercalciuria may also be the first sign of healing of osteomalacia (theoretically, osteomalacic bone is capable of taking up more calcium and phosphate than bone that is histologically normal). Patients may require higher doses for initial healing, and then doses may be somewhat decreased during the long-term "maintenance" phase, especially to minimize calciuria and effects on PTH and renal function.

Diarrhea and gastrointestinal upset frequently develop from phosphate administration. To minimize diarrhea, the phosphate dose should be increased gradually. If diarrhea develops, it is best to decrease (or stop) the dose of phosphate and slowly increase therapy as tolerated. Because hypercalcemia may develop from calcitriol therapy, patients should be given instructions on the symptoms of hypercalcemia, such as depression, confusion, anorexia, nausea, vomiting, polyuria, and dehydration. Serum biochemistries should be measured if a patient experiences any symptoms of hypercalcemia.

The most common and potentially serious complication of therapy is the development of nephrocalcinosis.[52] With the widespread use of renal ultrasound, nephrocalcinosis has been noted with increasing frequency. Studies that are mostly cross-sectional indicate that nephrocalcinosis occurs in 50% to 80% of patients with XLH on conventional therapy, including adults and children. Hypercalciuria and hypercalcemia may contribute to (or at least aggravate) this problem. In most cases, the nephrocalcinosis is observed without evident changes in GFR; however, its long-term effect on kidney function remains uncertain. Data are sparse regarding chronic kidney disease in general in XLH, but some studies have indicated that 8% to 9% of adults with XLH have at least some degree of chronic kidney disease, which complicates management of their bone disease.[69] End-stage renal disease appears to be rare, but has been reported.

Hyperparathyroidism is a complex feature of XLH and its treatment. Prior to starting any treatment patients commonly have secondary hyperparathyroidism, likely the consequence of FGF23-mediated impairments in vitamin D activation. This often improves as calcitriol treatment begins. However, phosphate salts specifically trigger rises in PTH via their effect to decrease serum calcium after dosing, also contributing to the development of hyperparathyroidism. High phosphate doses, especially with insufficient calcitriol, can lead to prolonged secondary hyperparathyroidism with multigland hyperplasia, which converts to tertiary (or hypercalcemic) hyperparathyroidism in some patients. Secondary hyperparathyroidism occurs in up to 83% of patients with XLH, which can sometimes resolve with dose adjustment.[69] However, tertiary hyperparathyroidism occurs in 4% of children and 25% to 30% of adults.[69] In tertiary hyperparathyroidism, renal function may decline, necessitating a reduction in the dose of phosphate and calcitriol or cessation of therapy, with corresponding limitations in effectiveness at treating osteomalacic bone disease. Typically, all the parathyroid glands are abnormal in tertiary hyperparathyroidism, and removing a single gland is insufficient to resolve hypercalcemia. The recurrence rate after surgery was high (75%) in a small study at a median follow-up of 6 years, and hypercalcemia has recurred even in some patients with four-gland resection with reimplantation of a piece of a gland.[69] One risk of the procedure is complete hypoparathyroidism, which greatly complicates management, as patients have both hypocalcemia and hypophosphatemia, with both hypercalciuria and hyperphosphaturia. Cinacalcet has been used to manage tertiary hyperparathyroidism, with mixed results.[69]

Although treatment complications cannot be prevented entirely, careful monitoring may minimize treatment-related problems. Serum calcium, phosphorus, and creatinine levels and urine calcium and creatinine concentrations should be monitored monthly while patients are on high-dose therapy and every 3 to 4 months while on maintenance therapy. A 24-hour urine phosphorus measurement is often useful to gauge compliance with therapy. Serum PTH concentration should be measured at 6- to 12-month intervals and should influence dose adjustments as appropriate. Renal ultrasounds should be assessed every 1 to 2 years. In adults restarting therapy, it is important to assess PTH and renal function and renal ultrasound at baseline, as these may be abnormal even years after stopping prior conventional therapy.

Burosumab. In preclinical animal studies, using murine antibodies to FGF23 improved the tubular reabsorption of phosphate, serum phosphorus, and 1,25(OH)$_2$D in the Hyp mouse model, resulting in improvements in mineral apposition rate, bone volume/total volume, and skeletal growth, and improved organization and mineralization of the Hyp mouse's rachitic growth plate, femur shape, and skeletal growth.[70]

Burosumab is a fully human IgG$_1$ monoclonal antibody against the N-terminal domain of FGF23; thus, it binds to both intact FGF23 and N-terminal FGF23 fragments. Burosumab was developed for treating XLH and TIO, administered subcutaneously. Its half-life is 13 to 19 days when administered subcutaneously. In children with XLH- the FDA approved dosing of burosumab is 0.8 to 1.2 mg/kg subcutaneously every 2 weeks, and in adults with XLH the approved dose is 1 mg/kg subcutaneously every 4 weeks, with a maximum dose of 90 mg (https://www.accessdata.fda.gov2020). Burosumab has also been approved for managing the osteomalacia and hypophosphatemia of TIO at doses from 0.4 to 2 mg/kg every 2 weeks in children or every 4 weeks in adults.

Unlike conventional therapy for XLH, by binding FGF23 and blocking its activity burosumab alters the renal transport of phosphorus, allowing clinicians to effectively and safely target normalizing serum phosphorus levels. Both adult and pediatric studies demonstrated that burosumab increases 1,25(OH)$_2$D, TMP/GFR, and serum phosphate after injection.[71,72] Following burosumab dosing, 1,25(OH)$_2$D peaks between 3 and 7 days later; TMP/GFR peaks approximately 7 days after injection, and serum phoshorus increases with a peak between 3 and 7 days after injection.[71] However, hyperphosphatemia may occur, requiring careful monitoring and dose decreases if this occurs. Burosumab is given as monotherapy; all clinical trials had patients undergo washout of conventional therapy for 1 week or more before starting burosumab.

The first phase II pediatric XLH trial was designed to establish both dose level and dose interval. Dosing burosumab every 2 weeks was found to provide a better serum phosphorus profile than every 4 weeks among children with XLH aged 5 to 12 years at enrollment.[72] Children dosed every 2 weeks also had greater improvement in rickets than those dosed every 4 weeks during this 64-week trial. Subsequently, every 2-week dosing in younger children aged 1 to 4 years also demonstrated increases in serum phosphorus and improvement in rickets and lower limb deformities.[73] The only active comparator randomized controlled trial of burosumab was conducted in children aged 1 to 12 years. In this trial, children aged 1 to 12 years with XLH had to have Rickets Severity Scores of 2 or more despite treatment with conventional therapy for a mean of 3.3 to 4.3 years between randomization groups.[74] After a washout period of 7 days, these children were randomized to restart conventional therapy or switch to burosumab for 64 weeks. The fasting serum phosphate remained low in the conventional therapy group, while the fasting serum phosphate increased into the normal range during treatment with burosumab. While both groups had improvements in rickets, greater improvements in radiographic rickets was seen in those receiving burosumab at week 40 (the primary endpoint) and at week 64. Lower limb deformity improved in these trials, though to a lesser degree than the changes in the growth plate during 64 weeks of treatment. There were also modest improvements in length/height noted during treatment with burosumab compared with conventional therapy that were similar to the growth improvements seen in the prior phase II study.

A phase III randomized double-blind placebo-controlled trial of burosumab was conducted in adults with XLH who had Brief Pain Inventory worst pain scores of greater than or equal to 4.[66] These patients had evidence of severe disease: at baseline approximately half of subjects had active fractures or psuedofractures, 99% had enthesopathy, and half had nephrocalcinosis. Participants received 1 mg/kg burosumab (up to 90 mg) or placebo every 4 weeks for 24 weeks, followed by open-label burosumab during a

24-week extension period. The primary outcome of normal mean serum phosphorus at midcycle of the dosing range (2 weeks post-dose) throughout the trial was achieved by 94% in the burosumab group versus 7.6% in the placebo group. Treatment with burosumab completely healed 43% of active fractures or psuedofractures at 24 weeks, versus only 7.7% in the placebo group. After 48 weeks of burosumab, 63.1% of active fractures and psuedofractures had completely healed.[66] This improved healing is an important treatment target, but the study also demonstrates the prolonged healing time that is often necessary for patients with XLH. Some patients may still require rodding for stabilization of psuedofractures. Burosumab also improved Brief Pain Inventory worst pain score, stiffness, physical function, and 6-Minute Walking Distance. During a parallel trial, 11 subjects had paired bone biopsies before and after 48 weeks of burosumab 1 mg/kg, demonstrating improvements in osteoid volume/bone volume, osteoid thickness, and mineralization lag time.[75]

Two clinical trials of burosumab for treatment of TIO have been conducted: one in the United States and one in Japan and Korea. In the trial in Japan and Korea, burosumab increased serum phosphorus, decreased pain, and improved walking distance.[76] Burosumab has been FDA-approved for TIO.[77]

The most common adverse event in children was injection site reactions, occurring in 57.7%.[72] Injection site reactions were less common in adults.[66] Restless legs syndrome emerged during the first multidose trial in adults[71] and occurred in approximately 11.8% of those in the burosumab arm and 7.6% of those in the placebo arm of the placebo-controlled trial. Since publication of these trials, it has become our practice to routinely query restless legs syndrome in all adults with XLH, and we have noted frequent occurrence even among patients not receiving any medical therapy, raising the possibility of restless legs as a feature of XLH. However, it is also clear that, in some patients, restless legs emerges or worsens after starting burosumab.

Hyperparathyroidism is not likely to be a long-term risk for burosumab, but long-term studies are needed. Actually, during clinical trials, PTH levels improved in adults, though the mean values remained elevated.[66] The data available from clinical trials so far do not indicate a difference in the rate of nephrocalcinosis with burosumab versus conventional therapy. Because the renal phosphate reabsorption is improved with burosumab, the risk of nephrocalcinosis long-term may be less. However, there are potential reasons for burosumab to at least carry some risk for nephrocalcinosis, including the rise in $1,25(OH)_2D$ after each burosumab dose and the potential risk for hyperphosphatemia with burosumab (small numbers of patients in adult clinical trials required dose decreases due to excessive phosphate levels), both of which could increase risk for nephrocalcinosis. Consequently, we recommend continuing to monitor renal ultrasounds in patients treated with burosumab. Kidney function did not worsen during the trials. However, burosumab is contraindicated in patients with moderate to severe renal disease. It should be noted that, in rat studies of chronic kidney disease, using an anti-FG23 antibody worsened hyperphosphatemia and vascular calcifications, leading to death.[78]

Many things remain unknown about the effects of burosumab in the long term. To date there is no evidence for any effect of burosumab on enthesopathy. In addition, the full effect of burosumab on development of adult height is also not yet known, nor to what degree burosumab may reduce the need for orthopedic surgeries in children or adults. Burosumab has not yet been adequately studied in pregnancy or lactation.

KEY POINTS

- The first step to appropriate medical therapy is making the correct diagnosis, as treatment and risks differ by condition.
- Chronic fibroblast growth factor-23 (FGF23)-mediated hypophosphatemia may be treated using either conventional therapy with active vitamin D analogs combined with phosphate salts or monotherapy with an anti-FGF23 antibody, burosumab.
- In children with X-linked hypophosphatemia, both conventional therapy and burosumab improved rickets, with greater improvement from burosumab.
- Medical therapy of chronic hypophosphatemic conditions require frequent and careful laboratory monitoring for both efficacy and safety.
- Important complications of therapy for chronic hypophosphatemic conditions, especially those mediated by FGF23, include nephrocalcinosis and hyperparathyroidism.
- Additional risks of anti-FGF23 therapy include restless legs syndrome and injection site reactions.

Autosomal Recessive Hypophosphatemic Rickets (OMIM No. 241520). ARHR is genetically heterogeneous, as ARHR has been found to be the result of inactivating mutations in the dentin matrix protein-1 gene (*DMP1*), mutations in the ectonucleotide pyrophosphatase/phosphodiesterase 1 gene (*ENPP1*), and mutations in the family with sequence similarity 20, member C (*FAM20C*) gene (which causes a variant of Raine syndrome). DMP1 is a member of the **s**mall **i**ntegrin-**b**inding ***li***gand, N-linked **g**lycoprotein (SIBLING) family and is highly and specifically expressed in osteocytes. Both *Dmp1*-null mice and patients with ARHR manifest rickets and osteomalacia with isolated renal phosphate wasting associated with elevated FGF23. Mutational analyses revealed that one ARHR family carried a mutation that ablated the DMP1 start codon (Met1Val), and a second family exhibited a deletion in the DMP1 C-terminus (1484–1490del).[79]

Mechanistic studies using the *Dmp1*-null mouse have demonstrated that loss of Dmp1 impairs osteocyte maturation, leading to markedly elevated FGF23 mRNA and protein expression. The hypophosphatemia results in pathological changes in bone mineralization[79] that can be largely, but not completely, abrogated by a high-phosphate diet in *Dmp1*-null mice. Importantly, *Dmp1*-null mice are biochemical phenocopies of the Hyp mouse, and patients with ARHR and XLH (as well as *Dmp1*-null and Hyp mice) share a distinctive bone histology characterized by periosteocytic lesions of nonmineralized bone.[79] Thus, these findings suggest that PHEX (mutated in XLH) may also have a role in osteocyte maturation in a parallel pathway to DMP1 that leads to overexpression of FGF23.

ENPP1 encodes a type II transmembrane glycoprotein that cleaves a variety of substrates, including phosphodiester bonds of nucleotides and nucleotide sugars and pyrophosphate bonds of nucleotides and nucleotide sugars. ENPP1 likely functions to hydrolyze nucleoside 5' triphosphates to monophosphates, and also hydrolyzes diadenosine polyphosphates. ARHR patients who have *ENPP1* homozygous missense mutations have modestly elevated intact FGF23 and hypophosphatemia.[80] In bone, ENPP1 hydrolyzes ATP to pyrophosphate (PPi); therefore, the ENPP1 mutations could indicate that a balance of PP_i to inorganic phosphate phosphate may have a role in FGF23 production. Mutations in this gene are also known to be causative for generalized infantile arterial calcification and ossification of the posterior longitudinal ligament of the spine.

ARHR is also a variant of the typically lethal Raine syndrome, which due to loss-of-function mutations in the *FAM20C* gene (also known as Golgi casein kinase). Through exome sequencing, it was determined that compound heterozygous mutations in *FAM20C* were associated with increases in plasma levels of intact FGF23 but tapering hypophosphatemia with age, severe tooth decay from infancy, ectopic brain calcifications, and osteosclerosis.[81] Interestingly, FAM20C knockout mice are characterized by elevated FGF23, hypophosphatemia with inappropriately normal 1,25(OH)2 vitamin D concentrations, severe tooth defects, and a rickets phenotype.[82] Due to the noted similarities between the DMP1 knockout mice and FAM20C knockout mice, it was discovered that DMP1 levels were reduced in FAM20C knockout cells, perhaps producing the parallel phenotypes between these murine models. It was determined that FAM20C is an "atypical" kinase localized to the Golgi apparatus that phosphorylates a number of secreted SIBLING family members, including DMP1.[83] Thus, the lack of FAM20C may reduce DMP1 phosphorylation and inhibit its expression or function, thereby producing a "DMP1 knockout–like" phenotype in the FAM20C knockout mice. Why patients with ARHR type 3 and Raine syndrome have an osteosclerotic disease while FAM20C knockout mice have rickets is currently unclear.

Other Disorders Involving Fibroblast Growth Factor-23

Fibrous Dysplasia. Fibrous dysplasia (FD) is a disorder caused by activating somatic mutations in the *GNAS1* gene that encodes the α subunit of the stimulatory G protein, G_s.[84] The skeletal defects in FD are characterized by fibrous lesions and colocalized mineralization defects, which contribute to the morbidity in these patients. A significant proportion of FD patients also manifest various degrees of renal phosphate wasting and subsequent hypophosphatemia, which can lead to hypophosphatemic rickets and osteomalacia. Extraskeletal clinical manifestations of FD can occur, such as abnormal skin pigmentation, premature puberty, and hyperthyroidism; the disease is then referred to as *McCune–Albright syndrome* (MAS). In one study of FD patients, increased FGF23 serum levels correlated negatively to serum phosphate and $1,25(OH)_2D_3$ but positively to skeletal disease burden.[31] FGF23 mRNA and protein were localized to fibrous cells in the fibrous bone lesions of FD, as well as osteogenic and endothelial cells associated with microvascular walls in bone.[31] Therefore, it is evident that FGF23 plays an important role in the pathogenesis of the phosphate wasting that is often seen in FD/MAS.

The reason why the bone cells associated with lesions in FD overexpress FGF23 is not understood. Normally, FGF23 is expressed in osteogenic cells, but it is possible that improperly differentiated cells of FD lesions may have lost regulatory mechanisms required to suppress FGF23 production. Speculatively, this is analogous to FGF23 overexpression in TIO tumors, which are not subject to normal regulatory mechanisms.

Osteoglophonic Dysplasia (OMIM No. 166250). Activating mutations in fibroblast growth factor receptors 1 to 3 (FGFR1–3) are responsible for a diverse group of skeletal disorders. In general, mutations in FGFR1-2 cause syndromes involving craniosynostosis, whereas the dwarfing syndromes are associated with FGFR3 mutations. Osteoglophonic dysplasia (OGD) is a "crossover" disorder that has skeletal phenotypes associated with FGFR1 and FGFR2 mutations, as well as with FGFR3 mutations. In this regard, OGD patients present with craniosynostosis, prominent supraorbital ridge, and depressed nasal bridge, as well as with rhizomelic dwarfism and nonossifying bone lesions that show some similarity on x-ray to FD lesions. OGD is an autosomal dominant disorder that is caused by missense mutations in a highly conserved region comprising the ligand-binding and transmembrane domain of FGFR1, thus defining novel roles for this receptor as a negative regulator of long-bone growth. Of significance, three out of the four OGD patients studied had isolated renal phosphate wasting with inappropriately low $1,25(OH)_2D$ concentrations.[85] In one of these patients, a sample was available for analysis of plasma FGF23 concentrations, which were significantly elevated above control levels.[5] It was hypothesized that the associated metaphyseal lesions, which may be similar to FD lesions, produce FGF23, which causes renal phosphate wasting. Although only a few patients have been assessed, owing to the rarity of the disorder, OGD may have parallels with FD whereby the lesional burden of a patient is proportional to the FGF23 production and the extent of phosphate wasting. Interestingly, FGF23 production is stimulated by activation of FGFR1 in osteoblasts or osteocytes.[86]

Linear Nevus Sebaceous Syndrome. Linear nevus sebaceous syndrome (LNSS) is a rare congenital disorder involving cutaneous lesions characterized by papillomatous epidermal hyperplasia and excess sebaceous glands. Additional aberrations are often present in LNSS patients, including developmental defects of the brain that are associated with seizures, as well as eye complications. Hypophosphatemic rickets, may also present as part of LNSS, which usually presents within the first years of life, often with rickets, skeletal pain, and insufficiency fractures. LNSS has been associated with postzygotic activating mutations in three different genes: *HRAS*, *KRAS*, and *NRAS*. Patients with hypophosphatemia have elevated serum FGF23. Reports of improvements in hypophosphatemia following resection of skin lesions are mixed, and it is likely that the actual source of high FGF23 in these patients is the skeleton, as there are FD-like lesions in bone.[87]

αKlotho Overexpression. A case of severe hypophosphatemic rickets with hyperparathyroidism was identified in which the patient was negative for mutations in other genes responsible for heritable hypophosphatemias, including *FGF23*, *DMP1*, and *PHEX*. The patient was found to have a *de novo* translocation (t9:13) with a breakpoint adjacent to the gene encoding αKlotho (KL),[88] which is a single-pass membrane-bound renal coreceptor for FGF23. This chromosomal abnormality was associated with elevated circulating levels of cleaved or "cut" form of alpha-Klotho (cKL) that is known to result from proteolytic cleavage of KL at its extracellular juxtatransmembrane domain to produce a circulating isoform (see later for description of KL isoforms). The translocation patient had markedly elevated FGF23 in the face of prevailing hypophosphatemia, and hyperparathyroidism that necessitated gland debulking.[88] When cKL was delivered to mice via adenoassociated virus, a parallel phenotype was observed in the murine model characterized by markedly increased FGF23 despite severe hypophosphatemia. It was determined that elevated blood cKL resulted in increased FGF23 mRNA production in bone (150-fold), which would explain the high FGF23 concentrations despite low blood phosphate. *In vitro* studies indicated that cKL–FGFR interactions were involved in mediating cKL bioactivity.[89]

Disorders Associated With Reduced Fibroblast Growth Factor-23 Bioactivity

Hyperphosphatemic Familial Tumoral Calcinosis (OMIM No. 211900). Familial TC is a heritable autosomal recessive disorder characterized by ectopic calcified tumoral masses, dental abnormalities, and soft-tissue ectopic and vascular calcification. Biochemical abnormalities include hyperphosphatemia, increased TMP/GFR, and inappropriately normal or elevated $1,25(OH)_2D$ concentrations. Calcium and PTH are typically within the normal reference range, although suppressed PTH levels also occur. Biochemically, TC is the mirror image of the phosphate-wasting disorders XLH and ADHR. HHS is a rare disorder in which patients present with a similar biochemical profile to TC and have localized hyperostosis.[90]

Hyperphosphatemic Familial Tumoral Calcinosis/Hyperostosis-Hyperphosphatemia Syndrome Due to GALNT3 Mutations. The gene first identified for the heritable form of TC was UDP-*N*-acetyl-alpha-D-galactosamine: polypeptide *N*-acetylgalactos-aminyl transferase-3 (*GALNT3*), in which inactivating mutations were detected.[62] GALNT3 is expressed in the trans-Golgi network and initiates O-linked glycosylation of nascent proteins. In another family with a reported autosomal dominant TC, the clinical symptoms were in fact caused by two different biallelic *GALNT3* mutations, further supporting an autosomal recessive inheritance of this disorder.[89] The patients with TC due to *GALNT3* mutations were originally reported to have serum FGF23 levels approximately 30-fold above the normal mean when assessed with the C-terminal FGF23 ELISA.[62] Importantly, it was demonstrated that the TC patients did indeed have elevated C-terminal FGF23, but the same individuals had low circulating FGF23 when measured with the intact FGF23 ELISA.[1] These findings were then confirmed by demonstrating that loss of GALNT3 resulted in the production of nonfunctional FGF23 protein due to intracellular degradation.[91] FGF23 is O-glycosylated on residues within the $_{176}RHTR_{179}/S_{180}$ site (specifically at threonine 178); thus, the lack of glycosylation at this residue is thought to expose the SPC site and lead to degradation and destabilization of intact, active FGF23.[92]

HHS is due to inactivating mutations in GALNT3, and these patients also manifest inappropriate ELISA ratios of C-terminal to intact FGF23.[90] It has been shown that some of the HHS mutations are the same as those that result in TC,[90] indicating that TC and HHS represent ranges of severity within the same disease.

Hyperphosphatemic Familial Tumoral Calcinosis Due to FGF23 Mutations. TC is also caused by recessive mutations in the *FGF23* gene. Groups reported mutations giving rise to an amino acid change from a serine to a glycine at residue 71 (S71G),[93] or from a serine to a phenylalanine at residue 129 (S129F).[94] Other missense mutations have also been identified, including and M96T.[96] These FGF23 TC mutations (summarized in Table 53.2) occur within the FGF23 N-terminal FGF-like domain (residues 25–180). The TC alterations apparently destabilize intact FGF23, as supported by the findings that TC patients with FGF23 mutations have the same FGF23 ELISA pattern as GALNT3-TC patients, that is, markedly elevated C-terminal concentrations in concert with low intact values,[93] and the fact that these mutants are proteolytically cleaved prior to cellular secretion.[93,94] This cleavage is in part mediated by SPC proteases, inasmuch as addition of the ADHR mutations in tandem with the S71G TC mutations in the FGF23 cDNA resulted in rescue of full-length FGF23 production.[97] Thus, the common element in GALNT3-TC and FGF23-TC is the lack of secretion of intact FGF23. This lack of active FGF23 then results in elevation of serum phosphate through increased renal reabsorption, which in turn most likely results in elevated secretion of nonfunctional FGF23 fragments through a positive feedback cycle.

Hyperphosphatemic Familial Tumoral Calcinosis Due to Alpha-Klotho Mutations. FGF23 is a member of a class of FGFs including FGF19 and FGF21 that are endocrine, as opposed to paracrine/autocrine, factors. FGF23 requires the coreceptor KL for bioactivity, whereas FGF19 and FGF21 require beta-Klotho.[98,99] KL-null mice have severe calcifications, as well as markedly elevated serum phosphate,[100] which parallels Fgf23-null mice[101] and TC patients. Both the KL-null and Fgf23-null mice, however, have more severe phenotypes than that observed in TC patients. Importantly, the defects in the KL-null and Fgf23-null mice can largely be ameliorated with a low-phosphate diet to reduce serum phosphate. In parallel with Fgf23-null mice, KL-null mice have increased NPT2a in the proximal tubule,[102] indicating that the hyperphosphatemia in these animals is secondary to increased renal reabsorption of phosphate.

KL is produced as two isoforms due to alternative splicing of the same gene. Membrane-bound KL (mKL) is a 130-kD single-pass transmembrane protein characterized by a large extracellular domain and a very short (10-residue) intracellular domain that does not possess signaling capabilities. A secreted form of KL (sKL) is approximately 80 kD and arises from splicing within the *KLOTHO* gene exon 3 to result in a KL protein that does not contain the transmembrane domain and could be secreted into the circulation.[103] This form of KL, however, was not detected in human or mouse blood or cerebrospinal fluid.[104] The primary circulating form of KL is cKL, which results from proteolytic cleavage of mKL at its extracellular juxtatransmembrane domain by ADAM10/17 and BACE protease activity.[105]

The most likely mechanism for FGF23 signaling through KL is the recruitment of canonical FGFRs to form active signaling complexes. One group has identified a specific complex between FGFR1c and KL.[98] In contrast, others demonstrated that multiple FGFRs (FGFR1c, FGFR3c, and FGFR4) can interact with KL and FGF23 and signal through mitogen-activated protein kinase cascades.[106] Within the kidney, KL localizes to the proximal and distal tubules.[102,107] FGF23 is known to mediate its effects on NPT2a, NPT2c, and the vitamin D metabolizing enzymes within the proximal tubule.[21,51] FGF23 may also have effects on maintaining calcium and sodium reabsorption in the distal tubule. Because KL is a coreceptor for FGF23, mutations in the gene encoding this protein were sought as candidate causes for TC in a 13-year-old female with hypothesized end-organ resistance to renal FGF23 activity. This patient presented with hyperphosphatemia, hypercalcemia, elevated PTH, elevated intact and C-terminal FGF23 over 100- to 550-fold elevation of the normal means[108] (in contrast to the differential C-terminal to intact ELISA ratios in GALNT3- and FGF23-TC), and ectopic calcifications in the heel and brain. She had normal pubertal development, and her disease paralleled KL-null mice with regard to ectopic calcifications and dramatic elevation of circulating FGF23.[99] This patient was shown to have a recessive mutation in a highly conserved residue (Histidine193Arginine, or H193R) in the extracellular domain of KL (the "KL1" domain). Mutant KL expression was markedly reduced *in vitro* compared to that of wild-type KL, which resulted in a striking reduction in the ability of KL to mediate FGF23-dependent signaling.[108] Thus, an inactivating H193R KL mutation results in a TC phenotype and demonstrates that KL is required for FGF23 bioactivity.

In sum, it is clear that, in human disorders of phosphate handling and the corresponding mouse models, increased FGF23 bioactivity is associated with renal phosphate wasting and inappropriately normal $1,25(OH)_2D$ concentrations, and that the converse biochemical relationships exist, with loss of FGF23 bioactivity in the hormone itself or in its receptor complex (summarized in Fig. 53.4).

Genetic Hypophosphatemia Not Mediated by Elevated FGF23

Several genetic conditions exist that cause renal phosphate losses and hypophosphatemia but are not mediated by elevated FGF23. Some examples are described in this section. A common feature of these conditions is that they are often associated with hypercalciuria, either due to compensatory rises in $1,25(OH)_2D$ concentrations in response to hypophosphatemia or due to concurrent renal calcium losses due to a generalized tubulopathy. In addition, some of these conditions, such as Dent disease and nephropathic cystinosis, are associated with progressive renal failure.

Hereditary Hypophosphatemic Rickets With Hypercalciuria.

Similar to the disease entities described earlier, HHRH is characterized by hypophosphatemia; however, HHRH is distinguished by elevated 1,25(OH)D concentrations and suppressed PTH. The distinguishing biochemical characteristic of this disorder compared with the FGF23-related diseases such as ADHR and XLH is the notable increase in serum 1,25(OH)D as a compensatory response to the prevailing

Fig. 53.4 Genes involved in fibroblast growth factor-23 (FGF23) activity. Summary of genes involved in gain of FGF23 bioactivity *(light gray boxes)* through intrinsic stabilization (*FGF23* gene [ADHR]) or overproduction (TIO; *PHEX* gene [XLH]; *DMP1* gene [ARHR]; *ENPP1* gene [ARHR]; FAM20c gene [Raine syndrome, ARHR]; cleaved alpha-Klotho overexpression) *(solid-line pathways),* and involved in loss of FGF23 bioactivity *(dark gray boxes)* through mutations that compromise intact FGF23 production (*FGF23* and *GALNT3* genes) or its signaling complex (*KL* gene) *(dashed-line pathways). DCT,* Distal convoluted tubule; *PT,* proximal tubule; *TIO,* tumor-induced osteomalacia; *ADHR,* autosomal dominant hypophosphatemic rickets.

hypophosphatemia. Affected individuals also have markedly elevated urine calcium excretion, with increased intestinal absorption of phosphorus and calcium that can lead to nephrolithiasis. Clinically, patients with HHRH have rickets and short stature. Additional analysis of this kindred revealed 21 members with "intermediate" phenotypes, which led to an initial hypothesis that HHRH was inherited through an autosomal codominant mode. This group of patients manifested hypercalciuria, mild hypophosphatemia, and elevated calcitriol levels but no apparent bony abnormalities.[109]

Using a genome-wide linkage scan in combination with homozygosity mapping, the disorder was mapped to a 1.6-Mb region on chromosome 9q34, which contains the *SLC34A3* gene that encodes NPT2c.[110] A recessive, single-nucleotide deletion was then identified in this gene (228delC). Subsequently, multiple additional loss of function mutations have been identified in NPT2c causing HHRH. One of the key physiologic implications of identifying disease-causing mutations in NPT2c was the fact that this transporter now appears to have a significant role in renal phosphate reabsorption throughout life and is not limited to perinatal phosphate homeostasis as previously hypothesized. The fact that NPT2c mutations lead to disease in humans but not in mice[18] may indicate that this transporter plays a more important role in humans than in mice.

Dent Disease. In contrast to XLH, which is X-linked dominant, Dent disease is an X-linked recessive form of hyphophosphatemia. Dent disease is also associated with hypophosphatemic rickets, but, because it is not FGF23-mediated, the $1,25(OH)_2D$ is elevated, with associated hypercalciuria. Dent disease has been demonstrated to be caused by inactivating mutations in the gene for chloride channel 5 or in *OCRL1*, and the resulting protein abnormalities impair lysosomal trafficking, causing renal tubulopathies.[111] Nephrocalcinosis and nephrolithiasis are important consequences of the hypercalciuria. Proteinuria is also a prominent feature, and consequently evaluation for proteinuria should be an important part of the clinical evaluation of children presenting with hypophosphatemia. Patients with Dent disease develop chronic kidney disease, which often progresses to end-stage kidney disease by adulthood.

Nephropathic Cystinosis. Nephropathic cystinosis is a systemic autosomal recessive disease caused by mutations in the *CTNS* gene that ecnodes the lysosomal cystine transporter cystinosin. Deficiency of cystinosin causes cystine to accumulate in lysosomes in many organs and tissues, resulting in tissue damage.[112] In the nephropathic form, Fanconi syndrome develops in infancy, resulting in urinary losses of electrolytes, glucose, amino acids, bicarbonate, calcium, and phosphate. The resulting hypophosphatemic rickets is complicated by hypercalciuria, and sometimes hypocalcemia may also occur. The resulting metabolic bone disease causes rickets and poor linear growth. Corneal cystine crystals can impair vision, while accumulation in the thyroid leads to hypothyroidism. Additional features can include a vacuolar myopathy and hypogonadism. The rickets is treated with phosphate, and sometimes active vitamin D may be added, but patients must be carefully monitored for hypercalciuria, which can limit this treatment.[111] Early recognition of cystinosis is important, because treatment with oral cysteamine can delay end-organ damage in the kidney and other tissues. Cysteamine enters lysosomes and converts cystine to cysteine and cysteine–cysteamine disulfide, which can then be transported out of the cell, thus removing the intracellular cystine.

However, cysteamine treatment does not generally alter the Fanconi syndrome.

Making these diagnoses is important, as they alter the management. In contrast to the FGF23-mediated hypophosphatemia associated with XLH or ADHR, phosphate supplementation is an effective treatment for HHRH, but oral calcitriol is contraindicated; calcitriol levels in this disease are already elevated, and hypercalciuria may worsen. However, treating the bone disease in HHRH may be limited by tolerability of the phosphate salts. Nephropathic cystinosis is treated with oral cysteamine, in addition to management of mineral metabolism abnormalities. Burosumab is not recommended in conditions that are not FGF23-mediated.

KEY POINTS

- Rare diseases of fibroblast growth factor-23 (FGF23) overproduction are due to a heterogeneous group of mutations.
- Hyperphosphatemic falmilial tumoral calcinosis is cause by mutations in FGF23 itself, alpha-Klotho, and genes responsible for intracellular processing of FGF23.
- Some diseases of phosphate metabolism are independent of FGF23, and these should be distinguished at the genetic level to ensure proper treatment courses.

POSSIBLE FUTURE THERAPEUTIC AVENUES

As noted above, the use of a neutralizing monoclonal antibody to FGF23 in XLH and TIO has become a reality. Whether a longer-term infusion derivative of burosumab would provide benefit remains to be determined. For hyperphosphatemic disorders, the most direct potential application for treatment is the use of recombinant FGF23 in hfTC. Several groups have demonstrated that inactivating mutations in *FGF23* lead to hfTC; thus, delivering recombinant FGF23 may completely resolve the disorder by directly treating the molecular defect through replacement of missing or mutant FGF23. Additional data are required to determine if FGF23 would be a potential treatment for GALNT3-mediated TC. Whether ADHR-mutant FGF23 (mutant at positions 176 and/or 179) would provide a "longer-acting" form of therapy as a result of stabilization of the full-length polypeptide compared to the labile wild-type form remains to be determined.

Acknowledgments

The authors would like to acknowledge the funding support of the National Institutes of Health through grants R21AR059278, R01DK112958, R01HL145528 (KEW), and AR068615 (MJE), as well as the Indiana CTSI. We thank Dr. F. Richard Bringhurst for contributions to earlier editions of this chapter.

KEY POINTS

- The clinical presentation of primary hyperparathyroidism (PHPT) has evolved from a highly symptomatic disorder to one that is asymptomatic in the majority of patients. Presentation, however, can vary depending on screening practices.
- Despite the rarity of overt bony complications in PHPT today, sensitive tools demonstrate evidence of skeletal involvement in both cortical and trabecular compartments.
- Surgery remains the only cure for PHPT. Although medical alternatives can be used to treat hypercalcemia or osteoporosis, there is no "medical parathyroidectomy." All symptomatic patients should undergo surgery. Evidence-based guidelines provide clinicians with criteria for recommending parathyroidectomy in asymptomatic PHPT.

INTRODUCTION

Primary hyperparathyroidism (PHPT) is characterized by hypercalcemia and elevated or inappropriately normal parathyroid hormone (PTH) levels. The disorder today bears few similarities to the severe condition described by Fuller Albright and others as a "disease of stones, bones, and groans" in the 1930s.[1] The skeletal hallmark of PHPT was *osteitis fibrosa cystica*, radiographically characterized by brown tumors of the long bones, subperiosteal bone resorption, distal tapering of the clavicles and phalanges, and "salt-and-pepper" erosions of the skull (Fig. 54.1). Nephrocalcinosis and nephrolithiasis were present in the majority of patients, and neuromuscular dysfunction with muscle weakness was also common. With the advent of the automated serum chemistry autoanalyzer in the 1970s, the diagnosis of PHPT was increasingly recognized, leading to a 4- to 5-fold increase in incidence.[2] Classic symptomatology, concomitantly, became much less frequent. In the United States and elsewhere in the developed world, symptomatic PHPT is now the exception, and more than three fourths of patients have no symptoms attributable to their disease, making PHPT a disease that has "evolved" from its classic presentation (Table 54.1). Symptomatic nephrolithiasis is still observed, although much less frequently than in the past. Now, radiologically evident bone disease is rare, but subclinical skeletal involvement can be readily detected by bone densitometry. This chapter describes the modern presentation, diagnosis, and management of PHPT.

RISK FACTORS, PATHOLOGY, AND ANATOMICAL LOCATION

PHPT results from excessive secretion of PTH from one or more of the parathyroid glands. The underlying cause of sporadic PHPT is unknown in most cases. Although external neck radiation and lithium therapy are risk factors for the development of sporadic PHPT, most patients do not report these exposures.[3,4] Chronically low calcium intake and higher body weight have also been recently described to be risk factors.[5,6] The genetic pathogenesis of sporadic PHPT is unclear in most patients, but genes regulating the cell cycle are thought to be important, given the clonal nature of sporadic parathyroid adenomas.

By far the most common pathological finding in patients with PHPT is a solitary parathyroid adenoma, occurring in 80% of patients.[7] In 2% to 4% of patients, PHPT is due to multiple adenomas. In approximately 15% of patients, all four parathyroid glands are involved.[8] Parathyroid carcinoma accounts for less than 1% of all cases of PHPT.[7] The etiology of four-gland parathyroid hyperplasia is multifactorial. There are no clinical features that definitively differentiate single versus multiglandular disease, but risk factors include inherited genetic syndromes such as multiple endocrine neoplasia (MEN) type 1 or type 2a and lithium exposure.

Parathyroid adenomas can be found in many unexpected anatomic locations. Parathyroid tissue embryonal migration patterns account for a plethora of possible sites of ectopic parathyroid adenomas. The most common locations are within the thyroid gland, the superior mediastinum, and the thymus.[8] Occasionally, adenomas are identified in the retroesophageal space, the pharynx, the lateral neck, and even in the alimentary submucosa of the esophagus. On histologic examination, most parathyroid adenomas are encapsulated and are composed of parathyroid chief cells. Adenomas containing mainly oxyphilic or oncocytic cells are rare, but can give rise to clinical PHPT.

KEY POINTS

- Primary hyperparathyroidism (PHPT) results from excessive secretion of parathyroid hormone from one or more of the parathyroid glands. The underlying cause of sporadic PHPT, the most common form, is unknown in most cases. A solitary parathyroid adenoma is the most common pathologic finding and is present in 80% of patients.

EPIDEMIOLOGY, DIAGNOSIS, AND OVERVIEW OF CLINICAL FEATURES

Incidence

The incidence of PHPT has changed dramatically over the last half century.[2,9] Before the advent of the multichannel autoanalyzer in the early 1970s, Heath et al. reported an incidence of 7.8 cases per 100,000 persons in Rochester, Minnesota. With the introduction of routine calcium measurements in the mid-1970s, this rate rose dramatically to 51.1 cases per 100,000 in the same community. After prevalent cases were diagnosed, the incidence declined to approximately 27 per 100,000 persons per year in the United States, until 1998, at which time another sharp increase was noted.[9] This second peak has been attributed to the introduction of osteoporosis screening guidelines and targeted testing in those with osteoporosis.[9] Recent works shows that the incidence of PHPT increases with age and is higher in women and Black Americans than in men and other racial groups, respectively.[10]

Greater appreciation of the catabolic potential of PTH in postmenopausal women with osteoporosis has led to measurement of PTH even in subjects who do not have hypercalcemia. This trend has led to the emergence of a new entity, normocalcemic PHPT (NPHPT).[11] This condition is characterized by normal serum calcium, elevated PTH, and exclusion of known causes of secondary hyperparathyroidism. The incidence of NPHPT is unknown, but recent studies suggest a prevalence ranging from 0.2% to 3.1%.[12,13]

Diagnosis and Differential Diagnosis

The diagnosis of PHPT is made when hypercalcemia and elevated PTH levels are present.

PTH levels that are inappropriately normal are also consistent with the diagnosis. The other major cause of hypercalcemia, malignancy, is readily discriminated from PHPT by a suppressed PTH level. Further, both the clinical presentation and biochemical profile of PHPT and hypercalcemia of malignancy help distinguish them. Patients with hypercalcemia of malignancy typically have severe and symptomatic hypercalcemia and advanced cancers that are clinically obvious. On the other hand, in PHPT most patients are asymptomatic, and the serum calcium level is typically mildly elevated (within 1 mg/dL of the upper limit of normal). Extremely rarely, a patient with malignancy will be shown to have elevated PTH levels resulting from ectopic secretion of native PTH from the tumor itself. Much more commonly, the malignancy is associated with the secretion of PTH-related protein (PTHrP), a molecule that does not crossreact in an intact PTH assay (discussed later). Finally, it is possible that a malignancy is present in association with PHPT. When the PTH level is elevated in someone with a malignancy, this is more likely to be the case than a true ectopic PTH syndrome.

Although 90% of patients with hypercalcemia have either PHPT or malignancy, the differential diagnosis of hypercalcemia includes a number of other etiologies, such as vitamin D intoxication, granulomatous disease, and others. With the exception of lithium and thiazide use and familial hypocalciuric hypercalcemia (FHH), virtually all other causes of hypercalcemia are associated with suppressed levels of PTH. If lithium and/or thiazides can be safely withdrawn, serum calcium and PTH levels that continue to be elevated 3 to 6 months later confirm the diagnosis of PHPT. FHH, on the other hand, is differentiated from PHPT by family history, typically (but not always) low urinary calcium excretion, and mutations in the calcium-sensing receptor gene or the more recently discovered associated genes *GNA11 and AP2S1*[14]. In addition, virtual complete genetic penetrance leads to its clinical appearance typically before the age of 30 years. It is extremely unusual for FHH to present without an antecedent history after the age of 50 years.

To distinguish PTH-mediated from non–PTH-mediated causes of hypercalcemia, PTH should be measured with an intact immunoradiometric (IRMA) or immunochemiluminometric assay, which readily discriminates between PHPT and hypercalcemia of malignancy. In PHPT, PTH concentrations are usually frankly elevated, but most often within two times the upper limit of normal. A minority may have PTH levels in the normal range, typically the upper range of normal. In PHPT, such values, although within the normal range, are clearly abnormal in a hypercalcemic setting. Several factors affect the PTH level in those with and without PHPT, including age, vitamin D levels, and renal function. Because PTH levels normally rise with age, the broad normal range (typically 10–65 pg/mL) reflects values for the entire population. In the younger individual (<45 years), one expects a narrower and lower normal range (10–45 pg/mL). Occasionally, the PTH level as measured will be as low as 20 to 30 pg/mL. Such unusual examples require a more careful consideration of other causes of hypercalcemia, but such individuals will usually be shown to have PHPT, because hypercalcemia that is not PTH-mediated suppresses the PTH concentration to levels that are either undetectable or at the lower limits of the reference range. Souberbielle et al.[15] have illustrated that the normal range is dependent on whether or not the reference population is vitamin D-deficient. When vitamin D-deficient individuals were excluded, the upper limit of the PTH reference interval decreased. Patients with PHPT and vitamin D deficiency have "heightened" PTH levels compared with those who are vitamin D-sufficient.[16]

On the other hand, renal dysfunction tends to elevate PTH levels via a number of mechanisms, including reduced clearance and degradation of PTH. Indeed, patients with PHPT and severe renal dysfunction (glomerular filtration rate <30mL/min) may also have higher PTH levels compared with those with better renal function.[17] In addition, the "intact" IRMA for PTH overestimates the concentration of biologically active PTH, particularly in renal failure. In 1998, Lepage et al.[18] demonstrated a large non-(1–84) PTH fragment that comigrated with a large aminoterminally truncated fragment (PTH[7–84]) and showed substantial crossreactivity in commercially available IRMAs. This large, inactive moiety constituted as much as 50% of immunoreactivity by IRMA for PTH in individuals with chronic renal failure. Recognition of this molecule led to the development of a new IRMA using affinity-purified polyclonal antibodies to PTH(39–84) and to the extreme N-terminal amino acid regions, PTH(1–4).[19] This "whole-PTH" or third-generation assay detects only the full-length PTH molecule, PTH(1–84). This assay has clear utility in uremic patients, but in PHPT both assays are equally useful.[18,20] Using the third-generation assay for PTH(1-84), a second molecular form of PTH(1-84) that is immunologically intact at both extremes has been identified. This molecule reacts only poorly in second-generation PTH assays. It represents less than 10% of immunoreactivity in normal individuals and up to 15% in renal failure patients. In a limited number of patients with a severe form of PHPT, or with parathyroid cancer, it may be overexpressed.[21]

PHPT can be discriminated from secondary and tertiary hyperparathyroidism by its different biochemical profile. Secondary hyperparathyroidism is associated with an appropriate elevation in PTH in response to a hypocalcemic provocation and either a frankly low or normal serum calcium level. Secondary hyperparathyroidism is often caused by vitamin D deficiency. Other causes include malabsorption, kidney disease, or hypercalciuria. Infrequently, patients with secondary hyperparathyroidism may become hypercalcemic, and will ultimately be found to have PHPT, when the underlying condition (for example, vitamin D deficiency) is corrected.[8] In these cases, the hypercalcemia of PHPT was "masked" by the coexisting condition. On the other hand, tertiary hyperparathyroidism describes a condition in which prolonged, severe

TABLE 54.2 Biochemical Profiles for Various Causes of Hypercalcemia and Hyperparathyroidism

Cause	Serum Calcium	Parathyroid Hormone (PTH)	Urine Calcium
Primary hyperparathyroidism	Elevated	Elevated or inappropriately normal	High or high normal
Hypercalcemia of malignancy and non–PTH-mediated hypercalcemia	Elevated	Suppressed	Typically high[a]
Secondary hyperparathyroidism	Normal or low	Elevated	Low in vitamin D deficiency, malabsorption, chronic renal failure High in idiopathic hypercalciuria
Tertiary hyperparathyroidism	Elevated	Elevated	Low before transplant
Familial hypocalciuric hypercalcemia	Elevated	Typically high-normal, or elevated	Typically low
Normocalcemic primary hyperparathyroidism	Normal	High	<350 mg/24 h[11]

[a] May vary by cause.

secondary hyperparathyroidism (as in end-stage renal disease) evolves into a hypercalcemic state owing to the development of autonomous functioning of one or more of the hyperplastic parathyroid glands. This can be observed in patients on dialysis or after renal transplant. Tertiary hyperparathyroidism is usually obvious from the history.

NPHPT describes a condition characterized by normal serum albumin-corrected calcium levels and ionized calcium values with an elevated PTH level. This condition can only be diagnosed when all known causes of secondary hyperparathyroidism have been excluded. Patients with NPHPT typically are diagnosed when PTH is measured in the course of an evaluation for low bone mass. NPHPT may represent the earliest manifestations of PHPT, a “forme fruste” of the disease. Several reports have appeared describing these individuals, with some patients progressing to overt hypercalcemia while under observation.[11,13]

Although the term “NPHPT” has been in use for decades, there has been considerable controversy concerning the accuracy of this designation. In many cases the increases in PTH levels were attributable to the limitations of available assay technology. The older midmolecule radioimmunoassay for PTH, previously in common use, measured hormone fragments in addition to the intact molecule. Spuriously elevated PTH levels, particularly in those with renal insufficiency in whom clearance of hormone fragments is impaired, were seen. Alternative explanations for hyperparathyroidism with NPHPT have been discovered, including medications, hypercalciuria, renal insufficiency, and certain forms of liver and gastrointestinal disease. In recent years, it has become clear that many patients designated as having NPHPT were vitamin D–deficient. Vitamin D deficiency with coexisting PHPT can give the semblance of normal calcium levels, when in fact the patients would have been hypercalcemic if the vitamin D levels were normal. Given that a possible view of NPHPT is a condition fostered by an element of vitamin D resistance, it is important to ensure vitamin D sufficiency. Although the Institute of Medicine stated that normal levels of vitamin D, as measured by 25-hydroxyvitamin D, are 20 ng/mL, it did not address conditions of abnormal mineral metabolism, such as PHPT. In particular, in NPHPT, we and others recommend that levels of 25-hydroxyvitamin D be raised, if necessary, to more than 30 ng/mL for at least 3 months to rule out an element of vitamin D insufficiency in this population. Biochemical profiles for the various causes of hypercalcemia and hyperparathyroidism are shown in Table 54.2.

Other Biochemical Features

In PHPT, serum phosphorus tends to be in the lower range of normal, but frank hypophosphatemia is present in less than one-fourth of patients. Hypophosphatemia, when present, is as a result of the phosphaturic actions of PTH. Average total urinary calcium excretion is at the upper end of the normal range, with approximately 40% of all patients experiencing hypercalciuria. Serum 25-hydroxyvitamin D levels tend to be at the lower end of the normal range. Although mean values of 1,25-dihydroxyvitamin D are in the high-normal range, approximately one third of patients have frankly elevated levels of 1,25-dihydroxyvitamin D.[8] This pattern is a result of the actions of PTH to increase expression of the 1-alpha hydroxylase that converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. A typical biochemical profile is shown in Table 54.3.

TABLE 54.3 Biochemical Profile in Primary Hyperparathyroidism ($n = 137$)

	Patients (Mean ± SEM)	Normal Range
Serum calcium	10.7 ± 0.1 mg/dL	8.2–10.2 mg/dL
Serum phosphorus	2.8 ± 0.1 mg/dL	2.5–1.5 mg/dL
Total alkaline phosphatase	114 ± 5 IU/L	<100 IU/L
Serum magnesium	2.0 ± 0.1 mg/dL	1.8–2.4 mg/dL
PTH (IRMA)	119 ± 7 pg/mL	10–65 pg/mL
25(OH)D	19 ± 1 ng/mL	30–80 ng/mL
1,25(OH)2D	54 ± 2 pg/mL	15–60 pg/mL
Urinary calcium	240 ± 11 mg/g creatinine	
Urine DPD	17.6 ± 1.3 nmol/mmol creatinine	<14.6 nmol/mmol creatinine
Urine PYD	46.8 ± 2.7 nmol/mmol creatinine	<51.8 nmol/mmol creatinine

Clinical Presentation

PHPT typically occurs in individuals in their middle years, with a peak incidence between ages 50 and 60 years.[8] However, the condition can occur at any age. Women are affected more frequently than men, in a ratio of approximately 3 to 4:1. Several different presentations of PHPT are possible and were originally described successively in time.[1,11,22] The classical symptomatic presentation was described first; later, asymptomatic PHPT emerged owing to biochemical screening, and most recently the normocalcemic variant was discovered, as described. However, these three forms of PHPT contemporaneously exist today. Which presentation predominates depends upon population- and geographic-specific screening practices. It is also postulated that vitamin D deficiency may affect clinical presentation. Vitamin D deficiency heightens PTH elevations, and this can worsen the hyperparathyroid process.[23] In regions of the world and populations where biochemical screening is not routine, and incidentally where vitamin D deficiency is endemic, symptomatic PHPT is the most common form, and PHPT will appear to be uncommon because it is only discovered when symptomatic.[24] In areas and populations where screening is routine, asymptomatic PHPT will predominate, and the incidence of PHPT is higher.[22]

This chapter focuses on asymptomatic PHPT, as it is the predominant form in the United States and in most of the developed world. At the time of diagnosis, most patients with PHPT do not exhibit classic symptoms or signs associated with disease. Clinically overt kidney stones and fractures are rare.[8] Constitutional complaints such as weakness, easy fatigability, depression, and intellectual weariness are seen with some regularity (see later discussion).[8] The physical examination is generally unremarkable. Band keratopathy, a hallmark of classic PHPT, occurs because of deposition of calcium phosphate crystals in the cornea, but is virtually never seen grossly. Even by slit-lamp examination, this finding is rare. The neck shows no masses. The neuromuscular system is normal. The sections following provide a detailed description of the multisystemic manifestations of PHPT.

Diseases associated epidemiologically with PHPT have included hypertension,[25] peptic ulcer disease, gout, or pseudogout.[26] More recently, celiac disease has been associated with PHPT.[27] Some concomitant disorders such as hypertension are commonly seen, but it is not established that any of these associated disorders are etiologically linked to the disease.

KEY POINTS

- Primary hyperparathyroidism is a common condition and most often occurs in postmenopausal women. Most often, the diagnosis is made when hypercalcemia is present with an elevated or inappropriately normal serum parathyroid hormone level. The clinical presentation has evolved from a highly symptomatic disorder to one that is asymptomatic in the majority of patients. Presentations, however, can vary depending on screening practices.

THE SKELETON

The classic radiologic bone disease of PHPT, *osteitis fibrosa cystica*, is rarely seen today in the United States.[8] Most series place the incidence of *osteitis fibrosa cystica* at less than 2% of patients with PHPT. The absence of classic radiographic features (salt-and-pepper skull, tapering of the distal third of the clavicle, subperiosteal bone resorption of the phalanges, brown tumors) does not mean that the skeleton is not affected. With more sensitive techniques, it has become clear that skeletal involvement in the hyperparathyroid process is actually quite common. This section reviews the profile of the skeleton in PHPT as it is reflected in assays for bone markers, bone densitometry, bone histomorphometry, and new skeletal imaging techniques.

Bone Turnover Markers

PTH stimulates both bone resorption and bone formation. Markers of bone turnover, which reflect those dynamics, provide clues to the extent of skeletal involvement in PHPT.

Bone Formation Markers. Osteoblast products, including bone-specific alkaline phosphatase activity, osteocalcin, and serum N-terminal propeptide of type I collagen, reflect bone formation. In PHPT, alkaline phosphatase, the most widely clinically available marker, can be mildly elevated, but in many patients total alkaline phosphatase values are within normal limits.[28] Osteocalcin is also generally increased in patients with PHPT.[29] Sclerostin is an important regulator of bone formation. Patients with PHPT have low sclerostin levels, suggesting that PTH downregulates sclerostin.[30]

Bone Resorption Markers. Markers of bone resorption include the osteoclast product, tartrate-resistant acid phosphatase, and collagen breakdown products such as hydroxyproline, hydroxypyridinium crosslinks of collagen, and N- and C-telopeptides of type 1 collagen (NTX and CTX). Urinary hydroxyproline, once the only available marker of bone resorption, no longer offers sufficient sensitivity or specificity to make it useful. Although urinary hydroxyproline was frankly elevated in patients with osteitis fibrosa cystica, in mild asymptomatic PHPT it is generally normal. Hydroxypyridinium cross-links of collagen, pyridinoline (PYD), and deoxypyridinoline (DPD), on the other hand, are often elevated in PHPT. They return to normal after parathyroidectomy.[31] DPD and PYD both correlate positively with PTH concentrations. Studies of NTX, CTX, and TRAP are limited. Thus, sensitive assays of bone formation and bone resorption are both elevated in mild PHPT.

Longitudinal Bone Turnover Marker Studies. Studies of bone turnover markers in the longitudinal follow-up of patients with PHPT indicate a reduction in these markers following parathyroidectomy. Bone markers decline after parathyroidectomy.[32] The kinetics of change in bone resorption versus bone formation following parathyroidectomy provide insight into skeletal recovery. We have found that markers of bone resorption decline rapidly following successful parathyroidectomy, whereas indices of bone formation follow a more gradual decrease.[31] Urinary PYD and DPD decreased significantly as early as 2 weeks following parathyroid surgery, preceding reductions in alkaline phosphatase. Similar data were reported from others. Minisola et al.[33] reported a drop in bone resorptive markers and no significant change in alkaline phosphatase or osteocalcin. The persistence of elevated bone formation markers coupled with rapid declines in bone resorption markers indicate a shift in the coupling between bone formation and bone resorption toward an accrual of bone mineral postoperatively.

Bone Densitometry

The advent of bone mineral densitometry as a major diagnostic tool for osteoporosis occurred at a time when the clinical profile of PHPT was changing from a symptomatic to an asymptomatic disease. This fortuitous timing allowed questions about skeletal involvement in PHPT to be addressed when specific gross radiologic features of PHPT had all but disappeared. Observations of skeletal health in PHPT made by bone densitometry have established the importance of this technology in the evaluation of all patients with PHPT. The Consensus Development Conference on Asymptomatic Primary Hyperparathyroidism in 1990 implicitly acknowledged this point when bone mineral densitometry was included as a separate criterion for clinical decision-making. Since that time, bone densitometry has become an indispensable component of both evaluating the patient and establishing clinical guidelines for management and monitoring.

The known physiologic proclivity of PTH to be catabolic at sites of cortical bone make a cortical site essential to any complete densitometric study of PHPT. By convention, the distal third of the radius

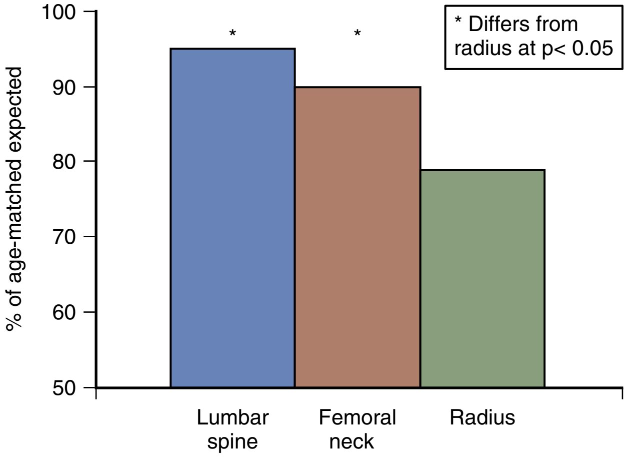

Fig. 54.2 Bone densitometry in primary hyperparathyroidism. Data are shown in comparison to age-matched and sex-matched normal subjects. Divergence from expected values is different at each site ($P < .0001$). (Data from Silverberg SJ, Shane E, de la Cruz L, et al. Skeletal disease in primary hyperparathyroidism, *J Bone Miner Res.* 1989;4:283–291.)

is the site used. The early densitometric studies in PHPT also showed another physiologic property of PTH, namely, to preserve bone at cancellous sites. The lumbar spine is an important site to measure, not only because it is predominantly cancellous bone, but also because postmenopausal women are at risk for cancellous bone loss. In PHPT, bone density at the distal third of the radius is diminished,[34] whereas at the lumbar spine it is only minimally reduced. The hip region, containing relatively equal amounts of cortical and cancellous elements, shows bone density intermediate between the cortical and cancellous sites (Fig. 54.2). The results support not only the notion that PTH is catabolic for cortical bone but also the view that PTH is generally protective against bone loss in cancellous bone.[35] In postmenopausal women, the same pattern was observed.[36] Postmenopausal women with PHPT, therefore, show a reversal of the pattern typically associated with postmenopausal bone loss. Rather than preferential loss of cancellous bone at the lumbar spine, the cortical site of the distal radius is more often affected in postmenopausal women with PHPT.

The bone density profile in which there is relative preservation of skeletal mass at the vertebrae and reduction at the more cortical distal radius is not always seen in PHPT. Although this pattern is evident in the vast majority of patients, some patients show evidence of vertebral osteopenia at the time of presentation. In our natural-history study, approximately 15% of patients had a lumbar spine Z score of less than –1.5 at the time of diagnosis.[37] Only half of these patients were postmenopausal women, so not all vertebral bone loss could be attributed entirely to estrogen deficiency. These patients are of interest with regard to changes in bone density following parathyroidectomy and are discussed in further detail later. The extent of vertebral bone involvement will vary as a function of disease severity. In the typical mild form of the disease, the pattern described earlier is seen. When PHPT is more advanced, there will be more generalized involvement, with involvement of the lumbar spine. When PHPT is severe or more symptomatic, all bones can be extensively involved. Vitamin D deficiency in mild asymptomatic PHPT seems to have minimal effect on bone mineral density (BMD), with only slightly reduced BMD at the one-third radius in those with low vitamin D.[38]

Bone Histomorphometry

Analyses of percutaneous bone biopsies from patients with PHPT have provided direct information that could only be indirectly surmised by bone densitometry and by bone markers. Both static and dynamic parameters present a picture of cortical thinning, maintenance of cancellous bone volume (Fig. 54.3), and a very dynamic process associated with high turnover and accelerated bone remodeling. Cortical thinning, inferred by bone mineral densitometry, is clearly documented in a quantitative manner by iliac crest bone biopsy.[39] Van Doorn et al.[40] demonstrated a positive correlation between PTH levels and cortical porosity. These findings are consistent with the known effect of PTH to be catabolic at endocortical surfaces of bone. Osteoclasts are thought to erode more deeply along the corticomedullary junction under the influence of PTH.

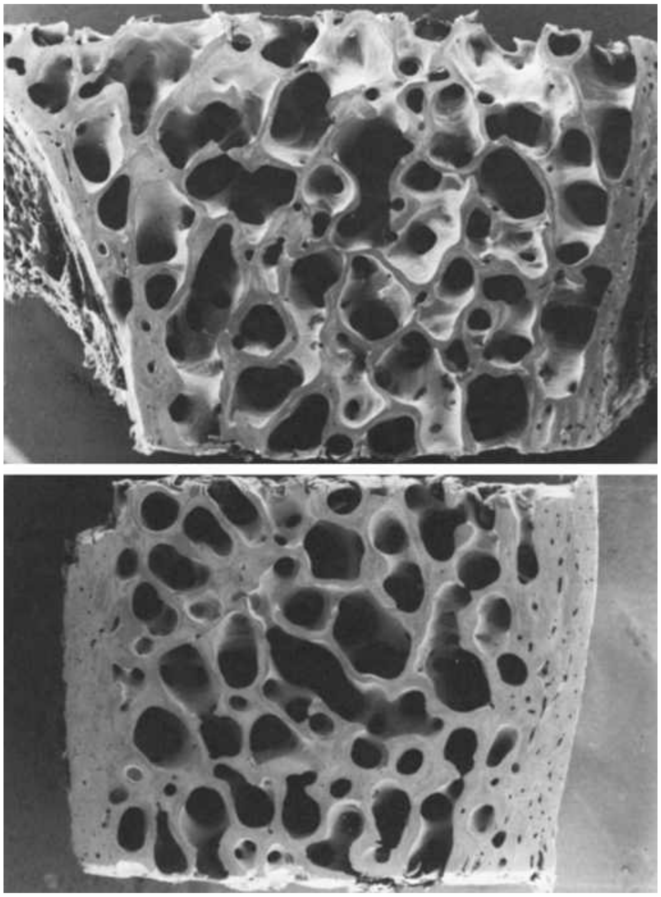

Fig. 54.3 Scanning electron micrographs of bone biopsy specimens from a normal subject (*bottom*) and an age- and sex-matched patient with primary hyperparathyroidism (*top*).The cortices of the hyperparathyroid sample are markedly thinned, but cancellous bone and trabecular connectivity appear to be well-preserved (×31.25). (From Parisien MV, Silverberg SJ, Shane E, et al. Bone disease in primary hyperparathyroidism, *Endocrinol Metab Clin North Am.* 1990;19:19–34.)

Histomorphometric studies have also contributed information about cancellous bone in PHPT. Again, as suggested by bone densitometry, cancellous bone volume is well preserved in PHPT. This is seen as well among postmenopausal women with PHPT. Several studies have shown that cancellous bone is actually increased in PHPT as compared with normal subjects.[41] When cancellous bone volume is compared among age- and sex-matched subjects with PHPT or postmenopausal osteoporosis, a dramatic difference is evident (Fig. 54.4). Whereas postmenopausal women with osteoporosis have reduced cancellous bone volume, women with PHPT have higher cancellous bone volume.[41] The region(s) of bone loss in PHPT is (are) directed toward the cortical bone compartment, with good maintenance of cancellous bone volume unless the PHPT is unusually active.

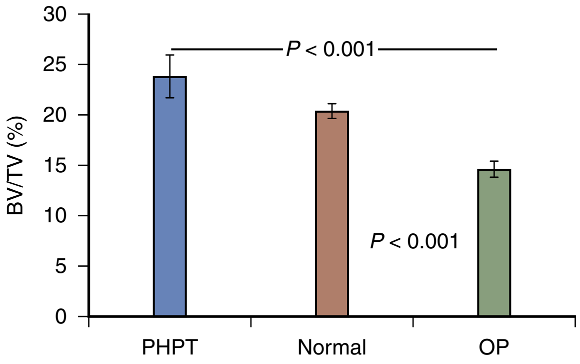

Fig. 54.4 Cancellous bone volume in primary hyperparathyroidism. Cancellous bone volume (*BV/TV*) was analyzed from bone biopsy specimens of the iliac crest. Comparisons are among 16 women with primary hyperparathyroidism (*PHPT*), 17 women with postmenopausal osteoporosis (*OP*), and 31 women with no known disorder of bone metabolism. Subjects were matched for age and other indices. (Data from Parisien M, Cosman F, Mellish RW, et al. Bone structure in postmenopausal hyperparathyroid, osteoporotic and normal women, *J Bone Miner Res.* 1995;10:1393–1399.)

In PHPT, age-related bone loss appears to be mitigated. In a study of 27 patients with PHPT (10 men and 17 women), static parameters of bone turnover (osteoid surface, osteoid volume, and eroded surface) were increased, as expected, in patients relative to control subjects.[42] However, in control subjects, trabecular number varied inversely with age, whereas trabecular separation increased with advancing age. These observations are expected concomitants of aging. In marked contrast, in the patients with PHPT, no such age dependency was seen. There was no relationship between trabecular number or separation and age in PHPT, suggesting that the actual plates and their connections were being maintained over time more effectively than one would have expected by aging *per se*. Thus, PHPT seems to retard the normal age-related processes associated with trabecular loss.

In PHPT, indices of trabecular connectivity are greater than expected, whereas indices of disconnectivity are decreased. When three matched groups of postmenopausal women were assessed (a normal group, a group with postmenopausal osteoporosis, and a group with PHPT), women with PHPT were shown to have trabeculae with less evidence of disconnectivity compared with normal women, despite increased levels of bone turnover.[42,43] Thus, cancellous bone is preserved in PHPT through the maintenance of well-connected trabecular plates. To determine the mechanism of cancellous bone preservation in PHPT, static and dynamic histomorphometric indices were compared between normal and hyperparathyroid postmenopausal women. In normal postmenopausal women, there is an imbalance in bone formation and resorption that favors excess bone resorption. In postmenopausal women with PHPT, on the other hand, the adjusted apposition rate is increased. Bone formation, thus favored, may explain the efficacy of PTH at cancellous sites in patients with osteoporosis. Assessment of bone remodeling variables in patients with PHPT shows increases in the active bone-formation period[41] (Table 54.4). The increased bone formation rate and total formation period may explain the preservation of cancellous bone seen in this disease.

More recently, further analysis of trabecular microarchitecture has taken advantage of newer technologies that have largely been confirmatory. In a three-dimensional analysis of transiliac bone biopsies using micro computed tomography technology, a highly significant correlation was observed with the conventional histomorphometry[44] described earlier. In comparison with age-matched control subjects without PHPT, postmenopausal women with PHPT had higher bone volume (BV/TV), higher bone surface area (BS/TV), higher connectivity density (Conn.D), and lower trabecular separation. There were also less marked age-related declines in BV/TV and Conn.D as compared with controls, with no decline in BS/TV. Using the technique of backscattered electron imaging to evaluate trabecular BMD distribution in iliac crest bone biopsies, Roschger et al.[45] showed reduced average mineralization density and an increase in the heterogeneity of the degree of mineralization, consistent with reduced mean age of bone tissue. Studies of collagen maturity using Fourier Transform Infrared Spectroscopy provide further support for these observations.[46] Bone strength, therefore, in PHPT has to take into account a number of factors related to skeletal properties of bone besides BMD.

New Imaging Technologies

Newer noninvasive skeletal imaging technologies offer new insight into the skeletal manifestations of PHPT beyond observations made by dual-energy x-ray absorptiometry (DXA) and radiography. The trabecular bone score (TBS) provides an indirect assessment of trabecular microstructure from the DXA image. In those without PHPT, it has been shown to predict fracture independently of BMD. In PHPT, TBS reveals trabecular microstructural deterioration at the spine, despite preserved BMD by DXA at this site.[47] High-resolution peripheral quantitative computed tomography (HRpQCT) is a technology that noninvasively and directly measures skeletal microstructure at the distal radius and tibia. Utilizing this technology, studies in patients with PHPT indicate not only cortical thinning, but additionally trabecular deficits at the radius and tibia (Fig. 54.5).[48] At the radius, trabeculae were fewer, thinner, and more widely and heterogeneously spaced. At the tibia, trabeculae were more heterogeneously spaced.[48] These deficits led to reduced stiffness when images were analyzed using microfinite element analysis, a technique that integrates structural and densitometric information from the HRpQCT image into an estimated of mechanical competence. These recent findings, pointing to abnormalities in the trabecular compartment of bone, help to account for the increased risk of vertebral fractures (see later) observed in PHPT that had remained unexplained before the advent of such technologies.[49,50] The difference in microskeletal abnormalities between the iliac crest bone biopsy data and HRpQCT may well reflect site-specific sampling differences.

Fractures

Fractures were a common clinical event in classic PHPT. In modern PHPT, one would anticipate, based on the BMD patterns observed with DXA, an increased risk of peripheral fractures but a reduction in vertebral fractures. Although not all studies are consistent, and many of the data are retrospective and/or cross-sectional, the majority of studies suggest an increased risk for vertebral fractures in patients with PHPT.[49,50] Moreover, recent data indicates that many vertebral fractures are in fact clinically silent.[50] The paradox of increased vertebral fracture risk despite preserved lumbar spine BMD in PHPT had remained unclear until the advent of TBS and HRpQCT, which clearly document trabecular deficits in addition to previously recognized cortical skeletal deterioration. Using the Danish National Patient registry and a nested case-control design, Ejlsmark-Svensson et al. recently showed that vertebral fractures in patients with PHPT occur at a higher BMD than in patients without PHPT, again pointing to the importance of other elements of bone quality in PHPT.[51] In one recent study, among asymptomatic PHPT patients, only those who met surgical guidelines showed a higher incidence of vertebral fractures compared with controls.[50]

TABLE 54.4 Wall Width and Remodeling Variables in Primary Hyperparathyroidism and Control Groups (Mean ± Standard Error of the Mean)

Variable	Primary Hyperparathyroidism (*n* = 19)	Control (*n* = 34)	*P*
Wall width (μm)	40.26 ± 0.36	34.58 ± 0.45	< .0001
Eroded perimeter (%)	9.00 ± 0.86	4.76 ± 0.39	< .0001
Osteoid perimeter (%)	26.84 ± 2.79	15.04 ± 1.09	< .0001
Osteoid width (μm)	13.39 ± 0.54	9.92 ± 0.36	< .0001
Single-labeled perimeter (%)	11.56 ± 1.63	4.47 ± 0.48	< .0001
Double-labeled perimeter (%)	10.41 ± 1.28	4.45 ± 0.65	< .0001
Mineralizing perimeter (%)	16.19 ± 1.75	6.68 ± 0.83	< .0001
Mineralizing perimeter/osteoid perimeter (%)	63.0 ± 5.0	44.04 ± 4.0	< .01
Mineral apposition rate (μm/day)	0.63 ± 0.03	0.63 ± 0.02	NS
Bone formation rate (μm 2/μm/day)	0.10 ± 0.01	0.042 ± 0.006	< .0001
Adjusted apposition rate (μm/day)	0.40 ± 0.04	0.29 ± 0.03	< .015
Activation frequency/year	0.95 ± 0.12	0.45 ± 0.06	< .0002
Mineralization lag time (days)	44.0 ± 6.5	57.0 ± 8.9	NS
Osteoid maturation time (days)	22.5 ± 1.8	16.6 ± 0.9	< .003
Total formation period (days)	129.2 ± 21.0	208.8 ± 32.5	NS
Active formation period (days)	67.8 ± 5.1	57.3 ± 2.3	< .05
Resorption period (days)	48.4 ± 7.3	84.8 ± 25.0	NS
Remodeling period (days)	172.5 ± 25.2	299.9 ± 55.1	NS

NS, Not significant.

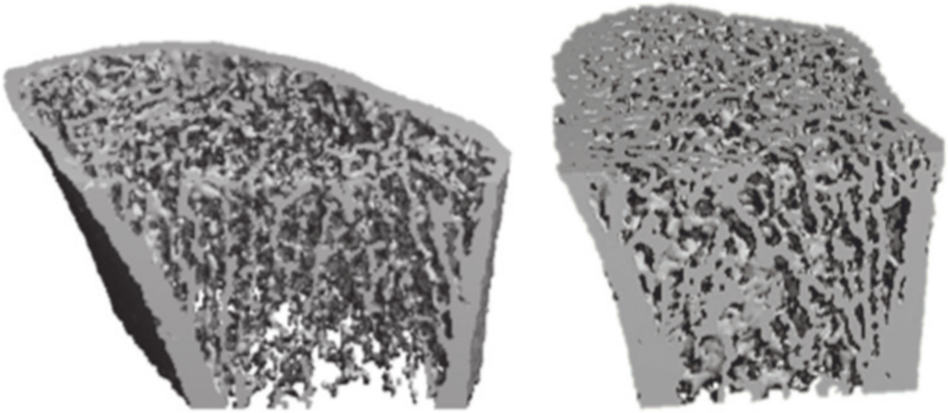

Fig. 54.5 High-resolution peripheral quantitative computed tomography images of the radius in a patient with primary hyperparathyroidism (PHPT; *left*) and a normal control (*right*). Trabecular deterioration is evident in PHPT. (From Stein EM, Silva BC, Boutroy S, et al. Primary hyperparathyroidism is associated with abnormal cortical and trabecular microstructure and reduced bone stiffness in postmenopausal women. *J Bone Miner Res.* 2012;28:1029–1040.)

The risk for hip fracture is not clearly increased in PHPT. In a study that focused on hip fracture, a population-based prospective analysis (mean of 17 years' duration; 23,341 person-years) showed women with PHPT in Sweden not to be at increased risk.[52] The Mayo Clinic experience with PHPT and risk of fracture reviewed 407 cases of PHPT recognized during the 28-year period between 1965 and 1992.[49] Fracture risk was assessed by comparing fractures at a number of sites with numbers of fractures expected based on gender and age from the general population. The clinical presentation of these patients with PHPT was typical of the mild form of the disease, with the serum calcium being only modestly elevated at 10.9 ± 0.6 mg/dL. The data from this retrospective epidemiologic study indicate that overall fracture risk was significantly increased at many sites such as the vertebral spine, the distal forearm, the ribs, and the pelvis. There was no increase in hip fractures. One might expect to see an increased incidence of distal forearm fractures as seen in the Mayo study, because the hyperparathyroid process tends to lead to a reduction of cortical bone (distal forearm) in preference to cancellous bone (vertebral spine). Unfortunately, there were no densitometric data provided in this study, so bone density could not be related to fracture incidence.

The impact of PHPT on fracture incidence appears complex and may be site-specific. This relationship is likely influenced by site-specific changes in areal bone density, bone size, and microstructure. Excess PTH would induce cortical thinning because of endosteal bone resorption but would also increase periosteal apposition, thus increasing bone diameter. Decreased areal bone density would increase fracture risk, whereas increased bone diameter and preserved microstructure at certain sites may protect against fractures. Prospective studies are needed to elucidate the site-specific risk of fracture in PHPT.

KEY POINTS

- The classic radiologic disease of primary hyperparathyroidism (PHPT), *osteitis fibrosa cystica*, is rarely seen today in the United States, but subclinical skeletal disease is often present. Dual-energy x-ray absorptiometry typically shows preferential loss of bone mineral density (BMD) at the distal one-third radius, a site that is rich in cortical bone. BMD at the lumbar spine, predominantly comprised of trabecular bone, tends to be preserved. The hip region, containing relatively equal amounts of cortical and trabecular elements, shows intermediate BMD values. Most data suggest fracture risk is increased in patients with PHPT.

NEPHROLITHIASIS AND RENAL FUNCTION

In the past, classic clinical descriptions of PHPT emphasized kidney stones as a principal complication of the disease. The cause of nephrolithiasis in PHPT is probably multifactorial. An increase in the amount of calcium filtered at the glomerulus resulting from hypercalcemia may lead to hypercalciuria despite the physiologic actions of PTH to facilitate calcium reabsorption. A component of absorptive hypercalciuria exists in this disorder. The enhanced intestinal calcium absorption is likely a result of increased production of 1,25-dihydroxyvitamin D, a consequence of PTH's action to increase the synthesis of this active metabolite.[53] Indeed, urinary calcium excretion is correlated with 1,25-dihydroxyvitamin D levels.[53] The skeleton provides yet another possible source for the increased levels of calcium in the glomerular filtrate. Hyperparathyroid bone resorption may contribute to hypercalciuria, and subsequently to nephrolithiasis, even though there is no convincing evidence to support this hypothesis. Finally, alteration in local urinary factors, such as a reduction in inhibitor activity or an increase in stone-promoting factors, may predispose some patients with PHPT to nephrolithiasis. It remains unclear whether the urine of patients with hyperparathyroid stone disease is different in this regard from that of other stone-formers.

Studies in the 1970s and 1980s documented a higher incidence of renal stone disease than do more recent reports.[8] Although the incidence of symptomatic nephrolithiasis today is much less common than it was in classical PHPT, kidney stones remain the most common manifestation of symptomatic PHPT, and symptomatic stones occur in 15% to20% of all patients (see Table 54.1).[8] Screening for asymptomatic nephrolithiasis indicates that the prevalence is actually much higher, and this is now recommended in the most recent set of guidelines on the management of asymptomatic PHPT.[54-56]

The etiology of why stones develop in some individuals with PHPT, but not others, has been debated since the 1930s, but is still not well understood. In the 1930s, it was generally accepted that bone and stone disease did not coexist in the same patient with classic PHPT.[1,57] Albright and Reifenstein[57] theorized that low dietary calcium intake led to bone disease, whereas adequate or high dietary calcium levels caused stone disease. Dent et al.,[58] who provided convincing evidence against this construct, proposed the existence of two forms of circulating PTH, one causing renal stones and the other causing bone disease. A host of mechanisms, including differences in dietary calcium, calcium absorption, forms of circulating PTH, and levels of 1,25-dihydroxyvitamin D, were proposed to account for the clinical distinction between bone and stone disease in PHPT.[58] Today, there is no clear evidence for two distinct subtypes of PHPT or that the process affecting the skeleton and kidneys occur in different subsets of patients. Cortical bone demineralization is as common and as extensive in those with and without nephrolithiasis.[59]

Although more recent work has suggested that 1,25-dihydroxyvitamin D plays an etiologic role in the development of nephrolithiasis in PHPT, not all studies are consistent with this premise.[59,60] Other investigations have shown risk factors for nephrolithiasis include younger age and male sex, whereas degree of hypercalcemia and hypercalciuria, PTH levels, and other urinary factors have less consistently been associated.[56,61,62] Hypomagnesuria has recently been associated with silent kidney stones in PHPT.[63]

Other renal manifestations of PHPT include hypercalciuria, which is seen in approximately 40% of patients, and nephrocalcinosis. The frequency of nephrocalcinosis is unknown, but it appears to be relatively uncommon today.[62] Although there were clear reports of renal impairment in early descriptions of PHPT, the prevalence of renal dysfunction (estimated glomerular filtration rate [eGFR] <60 mL/min) today in patients with mild PHPT is low, with recent studies suggesting rates of 15% to 17%.[64] Neither the severity of PHPT nor having a history of nephrolithiasis were risk factors for reduced eGFR in a 2014 study in those with mild PHPT; instead ,traditional risk factors, such as age, hypertension, use of antihypertensive medication, and fasting glucose levels were associated with poorer kidney function.[64] Longitudinal data are reassuring in this regard, as renal function remains stable in PHPT over long periods of follow-up.[65]

KEY POINTS

- Symptomatic nephrolithiasis is present in approximately 20% of patients today in the United States. Hypercalciuria is also common. With noninvasive imaging, nephrocalcinosis can also be seen, while overt renal dysfunction is rare.

OTHER ORGAN INVOLVEMENT

Cardiovascular System

Interest in the effect of PHPT on cardiovascular function is rooted in pathophysiologic observations of the hypercalcemic state. Hypercalcemia has been associated with increases in blood pressure, left ventricular hypertrophy (LVH), heart muscle hypercontractility, and arrhythmias.[8,66] Furthermore, evidence of calcium deposition has been documented in the form of calcifications in the myocardium, heart valves, and coronary arteries. The association of overt cardiovascular symptomatology with modern-day PHPT is unclear because of inconsistencies between studies. An explanation for the inconsistent results reported in the literature on the cardiovascular manifestations of PHPT relates to the fact that the clinical profile of the disease has changed. As a result, the cohorts that have been studied have varied greatly in the severity of their underlying disease. This is particularly true in terms of the serum calcium and PTH concentrations, with data from cohorts with marked hypercalcemia and hyperparathyroidism showing the most cardiovascular involvement. Because it is thought that both calcium and PTH can independently affect the cardiovascular system, such variability among cohorts can give rise to inconsistent results. Recent studies have focused on not only cardiovascular mortality, but also hypertension, coronary artery disease (CAD), valve calcification, LVH, carotid disease, and vascular stiffness.

Cardiovascular Mortality. There is little doubt that, in very active PHPT, cardiovascular mortality is increased.[8,66] Of some interest are postoperative observations in which the higher cardiovascular mortality rate persists for years after cure.[67] These observations differ markedly from those in which asymptomatic PHPT has been studied. Although limited, studies have not shown any increase in mortality.[68] The Mayo Clinic studies help to bring these observations together. In mildly hypercalcemic individuals, overall and cardiovascular mortality were reduced, but in those whose serum calcium was in the highest quartile, cardiovascular mortality was increased.[68] The idea that the more common asymptomatic form of PHPT is not associated with increased mortality is supported by data from studies in which more recently enrolled subjects had better survival than those who entered earlier and presumably had more active disease.[69]

Hypertension. Hypertension, a common feature of PHPT when it is part of a MEN syndrome with pheochromocytoma or hyperaldosteronism, has also been reported as being more prevalent in sporadic, asymptomatic PHPT than in appropriately matched control groups. The mechanism of this association is unknown, and the condition does not clearly remit following cure of the hyperparathyroid state.[66]

Coronary Artery Disease and Valve Calcification. Both calcium and PTH have independently been shown to be associated with coronary heart disease.[66] Aside from studies in which coronary atherosclerosis was seen in patients with marked hypercalcemia (16.8–27.4 mg/dL), the more recent literature has been controversial.[66] When CAD is present in PHPT, it is most likely owing to traditional risk factors rather than the disease itself.[66,70] Some studies have actually shown that in mild PHPT there is better exercise tolerance as determined by electrocardiogram.[71] Valve calcification, which is present in severe PHPT, has been shown to be more extensive (greater valve area) when present in those with mild PHPT versus controls[72,73] and is associated with increased PTH levels, but is not reversible with parathyroidectomy.[73]

Left Ventricular Hypertrophy. LVH is a strong predictor of cardiovascular disease and mortality.[66] LVH has been associated with PHPT in many, but not all, studies.[66] A 2015 metaanalysis indicated that parathyroidectomy is associated with a decline in left ventricular mass, and that higher levels of PTH preoperatively predict a greater cardiovascular benefit. However, dissociating disease severity from study design (randomized controlled trials [RCTs] included individuals with lower levels of calcium and PTH than those included in observational studies) was not possible.[74]

Vascular Function. Conflicting data exist regarding whether intima media thickness is increased in PHPT.[66] Multiple studies have reported increased vascular stiffness, sometimes associated with PTH levels, in mild PHPT, but its reversibility with parathyroidectomy is inconsistent.[66] Given conflicting data, most experts do not consider cardiovascular disease to be an indication for parathyroidectomy.[55]

Neurological, Psychologic and Cognitive Features

Descriptions of classical PHPT do indeed indicate neuropsychological features.[1] The extent to which these features remain a part of the modern picture of PHPT, as well as the exact mechanisms underlying them, is unclear. Perhaps the most common complaints have been those of weakness and easy fatigability. Classic PHPT was formerly associated with a distinct neuromuscular syndrome characterized by type II muscle cell atrophy.[75] Originally described by Vicale in 1949, the syndrome consisted of easy fatigability, symmetric proximal muscle weakness, and muscle atrophy. Both the clinical and electromyographic features of this disorder were reversible after parathyroid surgery.[76] In the milder, less symptomatic form of the disease that is common today, this disorder is rarely seen.

The "psychic groans" described by early observers of patients with classic PHPT remain a source of controversy today. Patients with PHPT often report some degree of behavioral and/or psychiatric symptomatology. A retrospective inquiry in patients with more severe disease showed a 23% incidence of psychiatric symptomatology ($n = 441$).[77] A number of studies suggest, however, that even "mild" PHPT (serum calcium <12 mg/dL) is associated with nonspecific symptoms such as depression, anxiety, fatigue, decreased quality of life (QoL), sleep disturbance, and cognitive dysfunction. Many, but not all, observational studies have indicated that these features improve after parathyroidectomy.[78] Three RCTs have investigated the reversibility of reduced QoL and psychiatric symptoms.[79-81] Despite being of similar design and using similar assessment tools, all three RCTs came to different conclusions; one RCT suggested that parathyroidectomy prevents worsening of QoL and improves psychiatric symptoms,[80] another RCT indicated no benefit, and a third RCT demonstrated improvement in QoL.[79,81]

Although less well-studied, some, but not all, studies have demonstrated reduced memory or impairment in other cognitive domains.[78,82] It is unclear if cognition improves after parathyroidectomy, because the results from studies in which longitudinal surgical control groups are compared with those undergoing PTX are inconsistent.[78] Recent work has turned to investigating the potential mechanisms that contribute to cognitive dysfunction in PHPT. Our latest studies have addressed this issue. We hypothesized that cerebrovascular dysfunction (i.e., vascular stiffness) may underlie cognitive changes in patients with PHPT. Although PTH correlated with cerebrovascular function as measured by transcranial Doppler, there was no consistent association between cerebrovascular function and cognitive performance.[83] In a separate study, we used functional magnetic resonance imaging (fMRI) to assess whether cerebral activation was altered by PHPT. fMRI is a noninvasive tool that maps brain function based on changes in blood flow.[84] We found that PHPT was associated with differences in task-related neural activation patterns, but that there no difference in cognitive performance. This may indicate compensation to maintain the same cognitive function, but there was no clear improvement in neural activation after PTX.[84] At present, most experts do not recognize cognitive or psychiatric symptoms as a sole indication for parathyroidectomy. Reasons for this include the failure to clearly demonstrate reversibility in RCTs, the inability to predict which patients may improve, and the lack of a clear mechanism.[55]

Gastrointestinal Manifestations

PHPT has long been considered to be associated with an increased incidence of peptic ulcer disease. Most recent studies suggest that the incidence of peptic ulcer disease in PHPT is approximately 10%, a figure similar to its percentage in the general population. An increased incidence of peptic ulcer disease is seen in patients with PHPT resulting from MEN1, in which approximately 40% of patients have clinically apparent gastrinomas (Zollinger–Ellison syndrome). In those patients, PHPT is associated with increased clinical severity of gastrinoma, and treatment of the associated PHPT has been reported to benefit patients with Zollinger–Ellison syndrome.[85] Despite this, current recommendations (Consensus Conference Guidelines for Therapy of MEN1) state that the coexistence of Zollinger–Ellison syndrome does not represent sufficient indication for parathyroidectomy, because medical therapy is so successful.[85]

Although hypercalcemia can underlie pancreatitis, most large series have not reported an increased incidence of pancreatitis in patients with PHPT with serum calcium levels less than 12 mg/dL. The Mayo Clinic experience from 1950 to 1975 showed that only 1.5% of those with PHPT exhibited coexisting pancreatitis, and alternative explanations for pancreatitis were found for several patients. Regarding pancreatitis in pregnancy in patients with PHPT, these conditions may coexist, but there is no evidence for a causal relationship between the disorders.

Other Systemic Involvement

Many organ systems were affected by the hyperparathyroid state in the past. Anemia, band keratopathy, and loose teeth are no longer part of the clinical syndrome of PHPT. Gout and pseudogout are seen infrequently, and their etiologic relationship to PHPT is not clear.

KEY POINTS

- Subclinical cardiovascular disease, neuropsychiatric and neurocognitive symptoms such as fatigue, reduced concentration and memory, and depression, and reduced quality of life have been reported in patients with primary hyperparathyroidism (PHPT). Specific attribution of these symptoms to PHPT and their reversibility with successful parathyroidectomy remain controversial. Gastrointestinal and rheumatological manifestations are rare, with an uncertain etiologic relationship to PHPT.

UNUSUAL PRESENTATIONS

Neonatal Primary Hyperparathyroidism

Neonatal PHPT is a rare form of the disorder caused by homozygous inactivation of the calcium-sensing receptor.[86] When present in a heterozygous form, it is a benign hypercalcemic state known as familial hypocalciuric hypercalcemia (FHH). However, in the homozygous neonatal form, hypercalcemia is severe, and the outcome is fatal unless recognized early. The treatment of choice is early subtotal parathyroidectomy to remove the majority of hyperplastic parathyroid tissue.

Primary Hyperparathyroidism in Pregnancy

PHPT in pregnancy is primarily of concern for its potential effect on the fetus and neonate. Potential complications of PHPT in pregnancy include spontaneous abortion, low birth weight, supravalvular aortic stenosis, and neonatal tetany. The last condition is a result of fetal parathyroid gland suppression by high levels of maternal calcium, which readily crosses the placenta during pregnancy. These infants, accustomed to hypercalcemia *in utero*, have functional hypoparathyroidism after birth, and can develop hypocalcemia and tetany in the first few days of life. Today, with most patients (pregnant or not) presenting with a mild form of PHPT, an individualized approach to the management of the pregnant patient with PHPT is advised. A recent retrospective study suggested that PHPT did not increase the risk of abortion, birth weight, length, or Apgar score.[87] Thus, many of those with mild disease can be followed safely, with successful neonatal outcomes without surgery. However, parathyroidectomy during the second trimester remains the traditional recommendation for this condition.

Acute Primary Hyperparathyroidism

Acute PHPT is known variously as *parathyroid crisis*, *parathyroid poisoning*, *parathyroid intoxication*, and *parathyroid storm*. Acute PHPT describes an episode of life-threatening hypercalcemia of sudden onset in a patient with PHPT. Clinical manifestations of acute PHPT are mainly those associated with severe hypercalcemia. Nephrocalcinosis or nephrolithiasis is frequently seen. Radiologic evidence of subperiosteal bone resorption is also commonly present. Laboratory evaluation is remarkable, not only for very high serum calcium levels, but also for extremely high PTH levels up to approximately 20 times normal. In this way, acute PHPT resembles, in biochemical terms, parathyroid carcinoma. A history of persistent mild hypercalcemia has been reported in 25% of patients. However, given the rarity of this condition, the risk of developing acute PHPT in a patient with mild asymptomatic PHPT is very low. Intercurrent medical illness with immobilization may precipitate acute PHPT. Early diagnosis with aggressive medical management followed by surgical cure is essential for a successful outcome. The initial impression of patients who present in this manner, without an antecedent history of hypercalcemia, is often mistaken for malignancy. However, the PTH level usually quickly clarifies the diagnosis as PHPT in most situations.

Parathyroid Cancer

An indolent yet potentially fatal disease, parathyroid carcinoma accounts for less than 0.5% of cases of PHPT. In contrast to patients with PHPT caused by benign parathyroid pathology, patients with parathyroid carcinoma typically have marked elevations in serum calcium and PTH. The cause of the disease is unknown, and no clear risk factors have been identified, except for hereditary syndromes. There is no evidence to support the malignant degeneration of previously benign parathyroid adenomas. Parathyroid carcinoma has been reported particularly in hyperparathyroidism-jaw tumor (HPT-JT) syndrome,[89] a rare autosomal disorder in which as many as 15% of patients will have malignant parathyroid disease. Because cystic changes are common, this disorder has also been referred to as *cystic parathyroid adenomatosis.* In HPT-JT, ossifying fibromas of the maxilla and mandible are seen in 30% of cases. Less commonly, kidney lesions, including cysts, polycystic disease, hamartomas, or Wilms tumors, can be present. Parathyroid carcinoma has also been reported in familial isolated hyperparathyroidism, in MEN1, and with somatic *MEN1* mutations.[90-92] However, recurrent parathyroid disease in MEN1 may mimic but might not actually be a result of malignancy. Only one case of parathyroid carcinoma has been reported in the MEN2A syndrome.[93]

Loss of the retinoblastoma tumor suppressor gene was formerly considered a marker for parathyroid cancer, but more recent studies do not unequivocally support this impression.[94] Work by Shattuck et al.[95] has provided new insights into the molecular pathogenesis of parathyroid cancer. Parathyroid carcinomas from 10 of 15 patients with sporadic parathyroid cancer carried a mutation in the *HRPT2* gene. The *HRPT2* gene that encodes for the parafibromin protein was shown to be mutated in a substantial number of patients with parathyroid cancer. Marcocci et al.[96] have reviewed this topic, pointing out a potential role for parafibromin in parathyroid cancer. In three of 15 patients with parathyroid cancer, Shattuck et al.[95] showed that the mutation was in the germline. The presence of the mutation in the germline suggests that this disease may be related in some way to the HPT-JT syndrome, in which this gene has been implicated.[95] In addition, there is an increased risk of parathyroid cancer in the HPT-JT syndrome. In fact, certain clinical features in patients with a germline mutation and in their relatives are indicative of the HPT-JT syndrome or phenotypic variants.[89]

Manifestations of hypercalcemia are the primary effects of parathyroid cancer. The disease tends not to have a bulk tumor effect, spreading slowly in the neck. Metastatic disease is a late finding, with lung (40%), liver (10%), and lymph node (30%) involvement seen most commonly. The clinical profile of parathyroid cancer differs from that of benign PHPT in several important ways.[96] First, no female predominance is seen among patients with carcinoma. Second, elevations in serum calcium and PTH are far greater. Consequently, the hyperparathyroid disease tends to be much more severe, with the classic targets of PTH excess involved in most cases. Nephrolithiasis or nephrocalcinosis is seen in up to 60% of patients; overt radiologic evidence of skeletal involvement is seen in 35% to 90% of patients. A palpable neck mass, distinctly unusual in benign PHPT, has been reported in 30% to 76% of patients with parathyroid cancer. Grossly, malignant glands are large, often exceeding 12 g. They tend to be adherent to adjacent structures. Microscopically, thick fibrous bands divide the trabecular arrangement of the tumor cells. Capsular and blood vessel invasion is common by these cells, which often contain mitotic figures.[96] Treatment is reviewed later.

KEY POINTS

- Parathyroid crisis, an episode of life-threatening hypercalcemia of sudden onset in a patient with primary hyperparathyroidism, is rarely seen today. Parathyroid carcinoma, a rare and indolent, but potentially fatal, condition is characterized by marked elevations in calcium and parathyroid hormone. Men and women are equally affected, with an average age at onset approximately 10 years younger than that of the much more common benign counterpart.

EVALUATION

The diagnosis of PHPT is confirmed by demonstrating an elevated or inappropriately normal PTH level in the face of hypercalcemia. Further biochemical assessment should include serum phosphorus, alkaline phosphatase activity, vitamin D metabolites, albumin, and creatinine. A morning 2-hour or 24-hour urine collection should be obtained for calcium and creatinine. A urinary bone resorption marker such as serum CTX or urinary N-telopeptide can be helpful. Bone densitometry is performed in all patients. It is important to obtain densitometry at three sites: the lumbar spine, the hip, and the distal third of the radius. Because of the differing amounts of cortical and cancellous bone at the three sites and the different effects of PTH on cortical and cancellous bone, measurement at all three sites gives the most accurate clinical assessment of skeletal involvement in PHPT. Bone biopsy is not routinely obtained in the evaluation of PHPT but is essential in research. In the most recent guidelines, spinal imaging is recommended to assess for clinically silent vertebral fractures.[55] This can be vertebral x-rays, vertebral fracture assessment, or TBS score, with the latter two obtained from the DXA image. Although symptomatic kidney stones are present in 15% to 20% of patients by history, the finding that many more have clinically silent nephrolithiasis has led to the recommendation to obtain renal ultrasound, computed tomography (CT), or abdominal x-ray to assess for either nephrolithiasis or nephrocalcinosis.

KEY POINTS

- Primary hyperparathyroidism is confirmed by demonstrating hypercalcemia and an elevated or inappropriately normal parathyroid hormone level. Further evaluation includes serum phosphorus, alkaline phosphatase activity, 25-hydroxyvitamin D, albumin, creatinine, estimated glomerular filtration rate, 24-hour urine calcium, and bone densitometry of the lumbar spine, hip and distal one-third radius. The newest guidelines also recommend obtaining spine and renal imaging to assess for subclinical vertebral fractures, kidney stones, and nephrocalcinosis.

NATURAL HISTORY

Since the early 1990s, new knowledge of the natural history of PHPT with or without surgery has been very helpful in guiding decisions regarding surgery in patients with asymptomatic PHPT. The authors and their colleagues have conducted the longest prospective observational trial.[22,97] This project began in 1984 in an effort to define the natural history of asymptomatic PHPT. The study included detailed analyses of pathophysiologic, densitometric, histomorphometric, and other skeletal features of PHPT.[22,97] Much of the information gleaned from that study has been summarized already in this chapter. The 15-year follow-up to this study constitutes the longest natural-history study of this disorder.[97]

Recommendations for surgery or observation were made based on the 1990 set of National Institutes of Health (NIH) guidelines, but both groups included patients who did or did not meet surgical guidelines. This is because some patients opted for surgery even if they did not meet the guidelines, whereas others opted for a conservative approach even if they did meet guidelines for surgery. As will be described in the following, this imperfectly designed study was followed by three studies that were truly randomized but were of shorter duration. The results with regard to natural history from all studies are remarkably concordant.

Natural History With Surgery

Successful parathyroidectomy results in permanent normalization of the serum calcium and PTH levels. Postoperatively, there is a marked improvement in BMD at all sites (lumbar spine, femoral neck, and distal one-third radius) amounting to gains greater than 10%.[22] The improvement is most rapid at the lumbar spine, followed by gains at the hip regions and the distal one-third radius during the 15-year follow-up (Fig. 54.6).[97] The improvements were seen in those who met and did not meet surgical criteria at study entry, confirming the salutary effect of parathyroidectomy in this regard on all patients.

Natural History Without Surgery

In subjects who did not undergo parathyroid surgery, serum calcium remained stable for approximately 12 years, with a tendency for the serum calcium level to rise in years 13 to 15.[97] Other biochemical indices such as PTH, vitamin D metabolites, and urinary calcium did not change for the entire 15 years of follow-up in the group as a whole. Bone density at all three sites remained stable for the first 8 to 10 years. However, after this period of stability, declining cortical BMD was seen at the hip and more dramatically at the distal one-third radius site. Although the numbers became limiting after 10 years of follow-up, it is noteworthy that a small majority of the subjects lost more than 10% of their BMD during the 15 years of observation. Even though this decline was observed in the majority of subjects, only 37% of subjects met one or more guidelines for surgery after the 15 years of follow-up.

Randomized Studies of the Natural History of Asymptomatic Primary Hyperparathyroidism

The long natural-history study of asymptomatic PHPT has added much to our knowledge about this disease throughout time. Subsequent randomized trials confirm the observational data but are limited by their shorter duration. In 2004, Rao et al.[98] reported on 53 subjects, assigned either to parathyroid surgery ($n = 25$) or to no surgery ($n = 28$). The follow-up lasted for at least 2 years. There was a significant effect of parathyroidectomy on BMD at the hip and femoral neck, but not the spine or forearm. In 2007 Bollerslev et al.[79] reported the interim results of their randomized trial of parathyroidectomy versus no surgery. This study from three Scandinavian countries was larger, with 191 patients who were randomized to medical observation or to surgery. After surgery, biochemical indices normalized, and BMD increased. In the group that did not undergo parathyroid surgery, BMD did not change. Also in 2007, Ambrogini et al.[81] reported the results of their randomized controlled trial of parathyroidectomy versus observation. Surgery

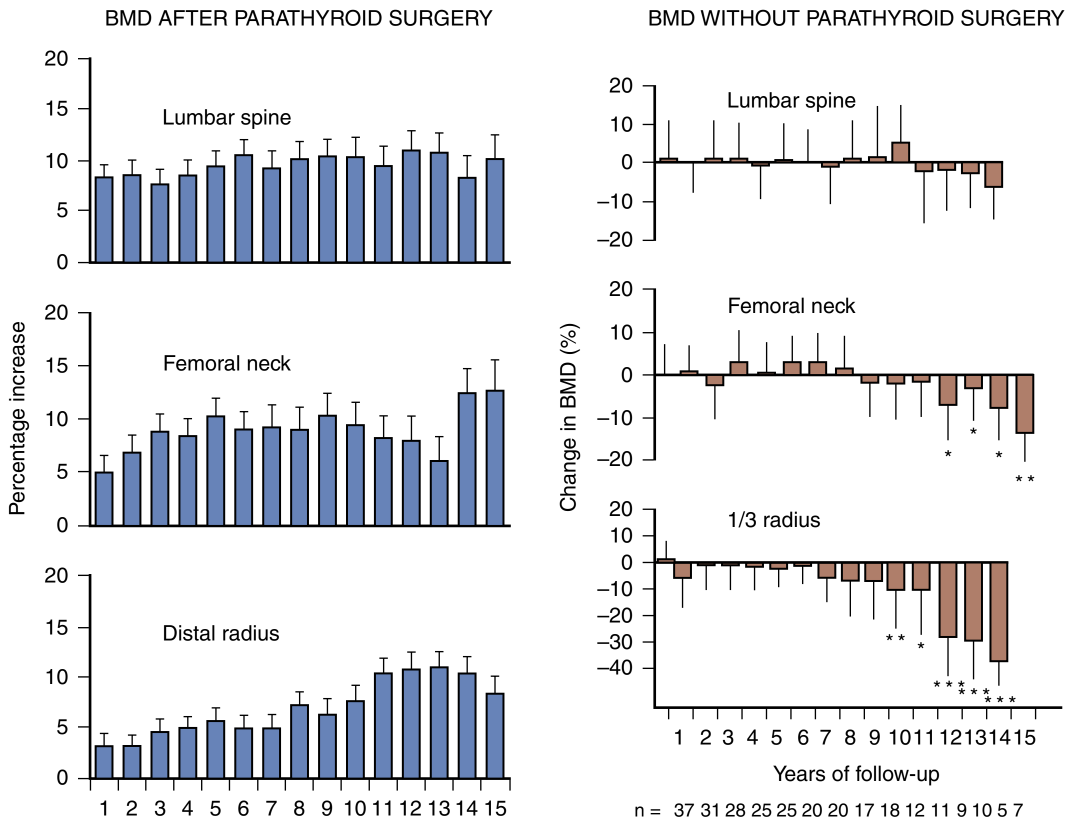

Fig. 54.6 Longitudinal course of bone density in primary hyperparathyroidism. Data are presented as percentage change from preoperative baseline bone mineral density (*BMD*) measurement by site following parathyroidectomy (*left*) or in patients followed with no intervention (*right*). (Data from Rubin MR, Bilezikian JP, McMahon DJ, et al. The natural history of primary hyperparathyroidism with or without parathyroid surgery after 15 years, *J Clin Endocrinol Metab.* 2008;93:3462–3470.)

was associated with a significant increase in BMD of the lumbar spine and hip after 1 year.

Whether fracture risk decreases after parathyroidectomy is not clear. The study by Bollerslev reported on vertebral fracture risk reduction at 5 years after initial treatment allocation. That study indicated that successful PTX versus observation was associated with a reduction in vertebral fracture risk that was of borderline statistical significance.[99]

KEY POINTS

- Successful parathyroidectomy results in cure. Serum calcium and parathyroid hormone levels become normal. Postoperatively, bone mineral density (BMD) improves at all sites. In those who are observed without parathyroidectomy, serum calcium and other biochemical indices remain stable for many years, but BMD may decline at cortical sites after 8 to 10 years. Approximately 40% of patients will develop an indication for surgery with long-term follow-up.

Guidelines for Parathyroidectomy

Parathyroidectomy remains the only currently available option to cure PHPT. As the disease profile has changed, questions have arisen concerning the advisability of surgery in asymptomatic patients. If asymptomatic patients have a benign natural history, the surgical alternative is not an attractive one. On the other hand, asymptomatic patients may display levels of hypercalcemia or hypercalciuria that cause concern for the future. Similarly, bone-mass measurements can be frankly low. In an effort to address such issues, there have been four consensus development conferences (in 1991, 2002, 2008, and 2013) on the management of asymptomatic PHPT. The most recent guidelines that emerged from the 2013 conference are helpful to the clinician faced with the asymptomatic hyperparathyroid patient: *all* symptomatic patients are advised to undergo parathyroidectomy.[55] Surgery is advised in asymptomatic patients with (1) serum calcium greater than 1 mg/dL higher than the upper limit of normal; (2) renal guidelines: reduction in creatinine clearance to less than 60 mL/min; urinary calcium excretion greater than 400 mg/24 h with increased stone risk; or presence of nephrolithiasis or nephrocalcinosis on renal imaging; (3) skeletal guidelines: reduced bone density T-score less than −2.5 at any site; or vertebral compression fracture on an imaging study; and (4) age younger than 50 years. The most recent guidelines are shown in Table 54.5. A noteworthy change in the guidelines reflects the fact that asymptomatic kidney stones and vertebral compression fractures are now considered indications for parathyroidectomy.

A number of points were discussed that did not lead to specific recommendations, including the issues of the neurocognitive and cardiovascular aspects of PHPT. The workshop panel also acknowledged a potential role of vitamin D deficiency in fueling processes associated with abnormal parathyroid glandular activity. Finally, the panel also reaffirmed the entity of NPHPT, but noted that there are insufficient data to provide evidence-based guidelines for management.

KEY POINTS

- Parathyroidectomy remains the only cure for primary hyperparathyroidism. *All* symptomatic patients should undergo parathyroidectomy. Surgery is advised in asymptomatic patients with (1) serum calcium greater than 1 mg/dL higher than the upper limit of normal; (2) reduction in creatinine clearance to less than 60 mL/min; urinary calcium excretion over 400 mg/24 hours with increased stone risk; or presence of nephrolithiasis or nephrocalcinosis on renal imaging; (3) reduced bone density T-score less than –2.5 at any site; or vertebral compression fracture on imaging; and (4) age younger than 50 years.

SURGERY

A large percentage of those patients who meet the surgical guidelines listed in Table 54.5 are asymptomatic. Some asymptomatic patients who meet surgical guidelines elect not to have surgery for varying reasons, including personal choice, intercurrent medical conditions, and previous unsuccessful parathyroid surgery. Conversely, there are patients who meet none of the NIH guidelines for parathyroidectomy but opt for surgery nevertheless. Physician and patient input remain important factors in the decision regarding parathyroid surgery.

Preoperative Localization of Hyperfunctioning Parathyroid Tissue

A number of imaging tests have been developed and have been applied singly or in combination to address the challenge of preoperative localization. The rationale for locating abnormal parathyroid tissue before surgery is that the glands can be notoriously unpredictable in their location. Although most parathyroid adenomas are identified in regions proximate to their embryologically intended position (the four poles of the thyroid gland), many are not. In such situations, previous surgical experience and skill are needed to locate the ectopic parathyroid gland. In such hands, 95% of abnormal parathyroid glands will be discovered and removed at the time of initial parathyroid surgery. However, in the patient with previous neck surgery, even expert parathyroid surgeons do not generally achieve such high success rates. Preoperative localization of the abnormal parathyroid tissue can be extremely helpful under these circumstances. Preoperative imaging is also necessary for any patient who will undergo parathyroidectomy using a minimally invasive approach. Imaging studies should not be used for the diagnosis of PHPT, because the sensitivity and specificity of various imaging modalities varies, with some having false-positive rates as high as 25%.[100]

Noninvasive Imaging. Noninvasive parathyroid imaging studies include technetium (Tc)-99m sestamibi scintigraphy, ultrasound, CT scanning, magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning (see also Chapter 56). Tc-99m sestamibi is generally regarded to be the most sensitive and specific imaging modality, especially when it is combined with single-photon emission CT (SPECT). For the single parathyroid adenoma, sensitivity has ranged from 80% to 100%, with a 5% to 10% false-positive rate. On the other hand, sestamibi scintigraphy and the other localization tests have a relatively poor record in the context of multiglandular disease.[100] The success of ultrasonography is highly operator-dependent. In centers where there is great expertise, this noninvasive approach is most attractive. Abnormalities identified by ultrasound as possible parathyroid tissue may prove to be a thyroid nodule or lymph node, which underscores the importance of the skill and experience of the ultrasonographer. Rapid spiral thin-slice CT scanning of the neck and mediastinum with evaluation of axial, coronal, and sagittal views can add much to the search for elusive parathyroid tissue, albeit with attendant higher radiation exposure. Four-dimensional (4D) CT has emerged as a promising method and consists of multiphase CT acquired at noncontrast, contrast-enhanced, arterial, and delayed phases. In a recent study, 4D CT was superior to sestamibi SPECT/CT.[101] MRI can also identify abnormal parathyroid tissue, but it is time-consuming and expensive. It is also less sensitive than the other noninvasive modalities. It can nonetheless be useful when the search with these other noninvasive approaches has been unsuccessful. PET with or without simultaneous CT scan can be used, but, like MRI, it is expensive and does not have the kind of experiential basis that make it attractive.[100] There are also specificity issues, because (^{18}F)-fluorodeoxyglucose, the scanning agent, accumulates in the thyroid, making differentiation between parathyroid adenoma and thyroid nodules difficult.

Invasive Imaging

Parathyroid Fine-Needle Aspiration. Fine-needle aspiration of a parathyroid gland, identified by any of the aforementioned modalities, can be performed, and the aspirate analyzed for PTH. This technique is not recommended for routine *de novo* cases. A theoretical concern with this approach is the possibility that parathyroid cells could be

deposited outside the parathyroid gland in the course of the aspiration. Autoseeding of parathyroid tissue would be an unwanted consequence of this procedure if it were to occur.

Arteriography and Selective Venous Sampling for Parathyroid Hormone. In situations where the gland has not been identified by any of the techniques described, the combination of arteriography and selective venous sampling can provide both anatomic and functional localization of abnormal parathyroid tissue. This approach, however, is costly and requires an experienced interventional radiologist. It is also performed in only a few centers in the United States. This approach is reserved for those individuals who have undergone previous unsuccessful parathyroid surgery in whom all other localization techniques have failed.

Surgical Approach

In the hands of an expert parathyroid surgeon, parathyroidectomy is successful, with infrequent complications. A standard surgical approach is the four-gland parathyroid exploration under general or local anesthesia, with or without preoperative localization. This approach has been reported to lead to surgical cure in more than 95% of cases (see Chapter 56).[102] Several alternative approaches have emerged that focus on the single gland and not the total four-gland neck exploration that was routinely used in the past. Unilateral approaches are appealing for a disease in which most often only a single gland is involved. These procedures include a unilateral operation in which the gland on the same side that harbors the adenoma is ascertained to be normal. Because multiple parathyroid adenomas are unusual, a normal parathyroid gland is considered by some to be sufficient evidence for single-gland disease. Another limited surgical approach that has emerged in many centers as the approach of choice is the minimally invasive parathyroidectomy (MIP). Preoperative parathyroid imaging is necessary, and the procedure is directed only to the site where the abnormal parathyroid gland has been visualized. Preoperative blood is obtained for comparison of the PTH concentration with an intraoperative sample(s) obtained after removal of the "abnormal" parathyroid gland. The availability of a rapid PTH assay in or near the operating room is necessary for this procedure. If the 10-minute postexcision PTH level falls by more than 50% compared with baseline, and into the normal range, the gland that has been removed is considered to be the sole source of overactive parathyroid tissue, and the operation is terminated. If the PTH level does not fall by more than 50%, into the normal range, the operation is extended to a more traditional one in a search for other overactive parathyroid tissue. There is a risk (albeit small) that the minimally invasive procedure may miss other overactive gland(s) that are suppressed in the presence of a dominant gland. The MIP procedure seems to be as successful, in the range of 95% to 98%, as more standard approaches. According to a recent metaanalysis that included more than 12,000 patients, MIP was associated with similar rates of success, disease recurrence, persistence, overall failure, and reoperation.[103] The operative time was significantly shorter, with a lower overall complication rate for MIP compared with bilateral neck exploration. In Europe, MIP is being performed with an endoscopic camera, but this does not offer any advantage other than a smaller incision.[104] Yet another variation on this theme is the use of preoperative sestamibi scanning with an intraoperative gamma probe to help locate enlarged parathyroid glands.

Immediate Postoperative Course

After surgery, biochemical indices return rapidly to normal.[22,97] Serum calcium and PTH levels normalize, and urinary calcium excretion falls by as much as 50%. Serum calcium levels no longer fall rapidly into the hypocalcemic range, a situation characteristic of an earlier time when PHPT was a symptomatic disease with overt skeletal involvement. The acute reversal of PHPT was associated with a robust deposition of calcium into the skeleton at a pace that could not be compensated for by supplemental calcium. Thus, postoperative hypocalcemia was routine and was sometimes a serious short-term complication ("hungry bone syndrome"). Occasionally, postoperative hypocalcemia still occurs, especially if preoperative bone turnover markers are markedly elevated or there is concomitant vitamin D deficiency. More typically, however, the early postoperative course is not complicated by symptomatic hypocalcemia.

After successful parathyroid surgery, biochemical indices of the disease return to normal, and BMD improves, as mentioned (Fig. 54.7). The capacity of the skeleton to restore itself is seen dramatically in

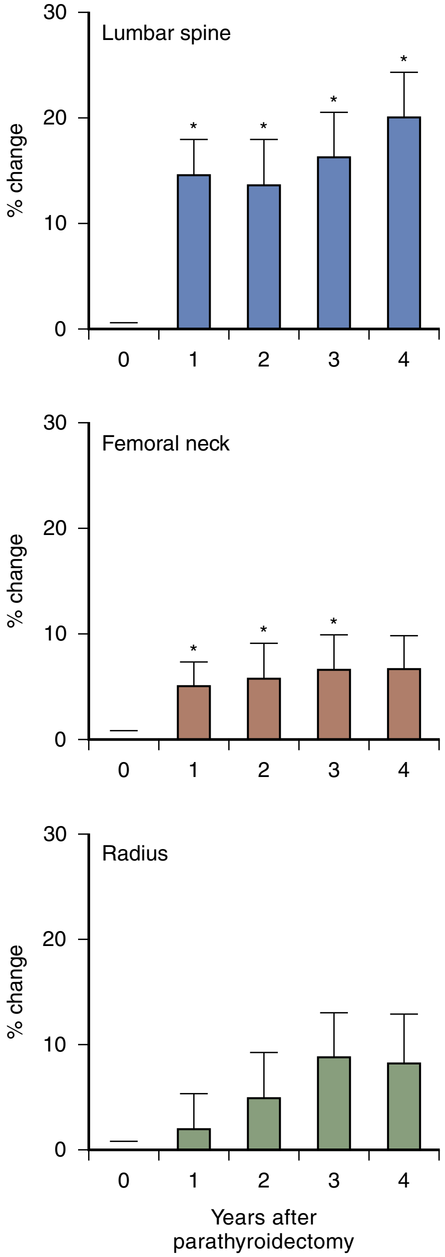

Fig. 54.7 Bone mineral density following parathyroidectomy in 14 primary hyperparathyroid patients with vertebral osteopenia. The cumulative percentage change from preoperative baseline (year 0) is shown for each site. *Asterisk* denotes change from baseline at $P < .05$. (Data from Silverberg SJ, Locke FG, Bilezikian JP. Vertebral osteopenia: a new indication for surgery in primary hyperparathyroidism, *J Clin Endocrinol Metab.* 1996;81:4007–4012.)

young patients with severe PHPT. Kulak et al.[105] reported two patients with *osteitis fibrosa cystica* who experienced increases in bone density that ranged from 260% to 430% in a period of 3 to 4 years following surgery.

KEY POINTS

- In the hands of an expert parathyroid surgeon, parathyroidectomy is successful in >95% of patients, with infrequent complications. The standard surgical approach is the four-gland parathyroid exploration. Most experts recommend preoperative parathyroid imaging for localization. Alternative approaches have emerged that focus on removal of the single abnormal gland, if identified preoperatively, as well as intraoperative parathyroid hormone measurements.

TABLE 54.6 Comparison of New and Old Management Guidelines for Patients With Asymptomatic Primary Hyperparathyroidism Who Do Not Undergo Parathyroid Surgery

Measurement	Older Guidelines	Newer Guidelines
Serum Calcium	*Semiannually*	*Annually*
24-h urinary calcium	Annually	Not recommended
Creatinine clearance	Annually	Not recommended
Serum creatinine	Annually	Annually
Bone density	Annually	Annually or biannually
Abdominal x-ray	Annually	Not recommended

MEDICAL MANAGEMENT

Patients who do not meet any surgical guidelines are often followed without intervention. The most recent guidelines for management of asymptomatic PHPT restated the position that it is reasonable to pursue a nonsurgical course of management for those who do not meet criteria for surgery, at least for a period of years. In those patients who are not going to have parathyroid surgery, the workshop[55] suggested a set of monitoring steps that are summarized in Table 54.6. This includes annual measurements of the serum calcium concentration, a calculated creatinine clearance, and regular monitoring of BMD.

Ideal medical therapy of PHPT would provide the equivalent to a medical parathyroidectomy. Such an agent would normalize serum calcium and PTH levels, as well as urinary calcium excretion, increase BMD and lower fracture risk, and reduce the risk of kidney stones. Unfortunately, no currently available single drug meets all these criteria. The following medications can achieve some of these goals and may be considered in patients not having surgery in whom it is desirable to lower serum or urinary calcium levels or increase BMD.

General Measures

Patients should be instructed to remain well hydrated and to avoid, if possible, medications that can increase serum calcium (e.g., thiazide diuretics). Prolonged immobilization, which can raise the serum calcium concentration further and induce hypercalciuria, should also be avoided.

Diet and Supplements

Dietary management of PHPT has long been an area of controversy. Many patients are advised to limit their dietary calcium intake because of the hypercalcemia. However, it is well known that low dietary calcium can lead to increased PTH levels in normal individuals.[106] In patients with PHPT, even though the abnormal PTH tissue is not as sensitive to slight perturbations in the circulating calcium concentration, it is still possible that PTH levels will rise when dietary calcium is tightly restricted. Dietary calcium could also be variably influenced by ambient levels of 1,25-dihydroxyvitamin D. In patients with normal levels of 1,25-dihydroxyvitamin D, Locker et al.[107] noted no difference in urinary calcium excretion between those on high (1000 mg/day) and low (500 mg/day) calcium intake diets. On the other hand, in those with elevated levels of 1,25-dihydroxyvitamin D, high-calcium diets were associated with worsening hypercalciuria. This observation suggests that dietary calcium intake in patients can be liberalized to 1000 mg/day if 1,25-dihydroxyvitamin D levels are not increased but should be more tightly controlled if 1,25-dihydroxyvitamin D levels are elevated. Although calcium supplements are not specifically recommended in those with PHPT and osteoporosis, small doses do not seem to exacerbate hypercalcemia or hypercalciuria if the diet is deficient.[8] Most experts recommend that patients with PHPT who are going to be followed without surgery have an intake of calcium that is consistent with nutritional guidelines for a normal population.

Recent guidelines recommend maintaining 25-hydroxyvitamin D at levels of 21 to 30 ng/mL, with conservative doses of vitamin D (600–1000 IU daily) based on data showing that vitamin D repletion lowers PTH levels. Higher levels of vitamin D may be beneficial. A 2014 RCT of cholecalciferol (2800 IU daily versus placebo) indicated that treatment increased 25-hydroxyvitamin D levels from 20 ng/mL to 37.8 ng/mL, lowered levels of PTH, and increased lumbar spine BMD, without having a deleterious effect on serum or urinary calcium levels.[108]

Pharmaceuticals

Phosphate. Oral phosphate can lower the serum calcium by up to 1 mg/dL.[109] A complex interplay of mechanisms leads to this moderating effect of oral phosphate. First, calcium absorption falls in the presence of intestinal phosphorus. Second, concomitant increases in serum phosphorus will tend to reduce circulating 1,25-dihydroxyvitamin D levels. Third, phosphate can be an antiresorptive agent. Finally, increased serum phosphorus reciprocally lowers serum calcium. Problems with oral phosphate include limited gastrointestinal tolerance, possible further increase in PTH levels, and the possibility of soft-tissue calcifications after long-term use. It is essentially not used any longer in the management of PHPT.

Estrogens and Selective Estrogen-Receptor Modulators. The earliest studies on the use of estrogen replacement therapy in PHPT date back to the early 1970s and indicated a 0.5- to 1.0-mg/dL reduction in total serum calcium levels, along with a lowering of urinary calcium.[8] Most studies indicated no change in PTH.[8] An RCT of conjugated estrogen (0.625 mg daily plus medroxyprogesterone 5 mg daily) versus placebo indicated that hormone-replacement therapy effectively increases BMD at all skeletal sites in patients with PHPT, with the greatest increases at the lumbar spine.[110] This RCT, however, did not confirm the calcium-lowering effect of earlier uncontrolled studies. In view of concerns expressed about chronic estrogen use in the Women's Health Study, estrogen use is not often recommended for medical management of hyperparathyroidism.

Raloxifene, a selective estrogen-receptor modulator, has been studied in PHPT, but the data are sparse. In a short-term (8-week) trial of 18 postmenopausal women, raloxifene (60 mg/day) was associated with a statistically significant, although small (0.5 mg/dL), reduction in the serum calcium concentration and in markers of bone turnover.[111] No long-term data or data on bone density are available.

Bisphosphonates and Denosumab. Bisphosphonates are conceptually attractive in PHPT because they are antiresorptive agents with an overall effect of reducing bone turnover. Although they do not affect PTH secretion directly, bisphosphonates could reduce serum and urinary calcium levels. Early studies with the first-generation bisphosphonates were disappointing, showing either no effect or only transient reductions in serum and urinary calcium.[8,112]

Alendronate has been studied most extensively in PHPT.[8] Several randomized controlled studies demonstrate that BMD of the lumbar spine and hip regions increases along with reductions in bone turnover markers.[8] In most studies, serum calcium was unchanged.[8] These results suggest that bisphosphonates may be useful in patients with low bone density in whom parathyroid surgery is not to be performed. One small study suggests that denosumab increases BMD in women with PHPT to a greater extent than patients without PHPT but with osteoporosis.[113]

Inhibition of Parathyroid Hormone. The most specific pharmacologic approach to PHPT is to inhibit the synthesis and secretion of PTH from the parathyroid glands, such as those that act on the parathyroid cell calcium-sensing receptor. This G protein-coupled receptor recognizes calcium as its cognate ligand. When activated by increased extracellular calcium, the calcium-sensing receptor signals the cell via a G protein-transducing pathway to raise the intracellular calcium concentration, which inhibits PTH secretion. Molecules that mimic the effect of extracellular calcium by altering the affinity of calcium for the receptor could activate this receptor and inhibit parathyroid cell function. Cinacalcet is one such compound and is now approved for the treatment of severe hypercalcemia in PHPT when surgery cannot be pursued. Studies conducted by the authors and their colleagues[114] indicate that this drug can reduce the serum calcium concentration to normal in PHPT (Fig. 54.8), but despite normalization of the serum calcium concentration, PTH levels do not return to normal; they do fall by 35% to 50% after administration of the drug. Urinary calcium excretion does not change; serum phosphorus levels increase but are maintained in the lower range of normal; and 1,25-dihydroxyvitamin D levels do not change. The average BMD does not change, even after 5 years of administration of cinacalcet.[114] Silverberg et al.[115] have shown that cinacalcet reduces calcium levels effectively in inoperable parathyroid carcinoma.

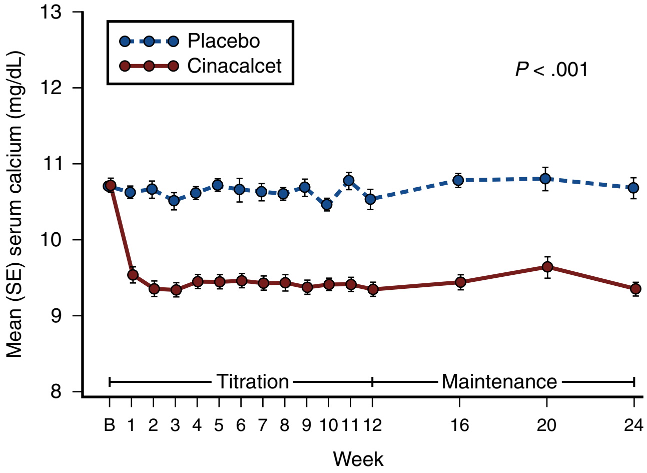

Fig. 54.8 Changes in serum calcium concentrations with administration of the calcimimetic cinacalcet (*solid line*) or placebo (*broken line*) in patients with primary hyperparathyroidism. *SE,* Standard error. (Data from Shoback DM, Bilezikian JP, Turner SA, et al. The calcimimetic cinacalcet normalizes serum calcium in subjects with primary hyperparathyroidism, *J Clin Endocrinol Metab.* 2003;88:5644–5649.)

HYDROCHLOROTHIAZIDE

Though avoiding agents that exacerbate hypercalcemia is generally recommended in patients with PHPT, a recent study has recently reexamined the role of thiazides in patients with PHPT. This retrospective analysis of 72 patients suggested that thiazides may not increase serum levels of calcium in PHPT as they can do in normal individuals. Hydrochlorothiazide (12.5–50 mg daily for 3.1 years on average) was associated with a decrease in urinary calcium excretion but no change in serum levels of calcium.[116] It is unclear if hydrochlorothiazide reduces the risk of nephrolithiasis. Given the heterogeneity of doses used, and the absence of data from larger, (preferably) randomized trials, recommending thiazide use routinely in PHPT is premature. However, thiazides could be considered in those who refuse surgery or who are poor surgical candidates but at high risk of nephrolithiasis in whom the benefit is thought to outweigh the risk, as long as serum levels of calcium are monitored regularly.

Treatment of Parathyroid Cancer

Surgery is the only effective therapy currently available for parathyroid cancer. The greatest chance for cure occurs with the first operation. After the disease recurs, cure is unlikely, although the disease may smolder for many years thereafter. The tumor is not radiosensitive, although there are isolated reports of tumor regression with localized radiation therapy. Traditional chemotherapeutic agents have not been useful. When metastasis occurs, isolated removal is an option, especially if only one or two nodules are found in the lung. Such isolated metastasectomies are never curative, but they can lead to prolonged remissions, sometimes lasting for several years. Similarly, local debulking of tumor tissue in the neck can be palliative, although malignant tissue is invariably left behind.

Chemotherapy has had a very limited role in this disease. Bradwell and Harvey[117] have attempted an immunotherapeutic approach by injecting a patient who had severe hypercalcemia resulting from parathyroid cancer with antibodies raised to her own circulating PTH. Coincident with a rise in antibody titer to PTH, previously refractory hypercalcemia fell impressively. A more recent report[118] provided evidence of the antitumor effect in a single case of PTH immunization in metastatic parathyroid cancer. Attention has been focused instead on control of hypercalcemia. Intravenous bisphosphonates have been used to treat severe hypercalcemia. Although efficacious in the short term, they do not provide an approach that allows long-term outpatient normalization of serum calcium levels. Denosumab has more recently been reported to treat resistant hypercalcemia in patients with parathyroid carcinoma.[119]

The calcimimetic agents offer a newer approach. Silverberg et al.[115] showed that cinacalcet is useful in the management of parathyroid cancer. The US Food and Drug Administration approved this calcimimetic for the treatment of hypercalcemia in patients with parathyroid cancer. Use of this agent in parathyroid cancer led to improvement in serum calcium levels and a decrease in symptoms of nausea, vomiting, and mental lethargy, which are common concomitants of marked hypercalcemia. There are no data on the effect of cinacalcet on tumor growth in parathyroid cancer. Similarly, there are no data on the use of a combination of cinacalcet and bisphosphonates in parathyroid cancer, the former used to decrease PTH secretion from the cancer, and the latter used to decrease release of calcium from the skeleton. Cinacalcet offers an option for control of intractable hypercalcemia when surgical removal of cancerous tissue is no longer an option.

KEY POINTS

- For those who will not or cannot undergo parathyroid surgery, medical alternatives include cinacalcet to reduce the serum calcium or bisphosphonates or denosumab to increase bone density. These approaches are not curative.

SUMMARY

This chapter has presented a comprehensive summary of the modern-day presentation of PHPT. Typically an asymptomatic disorder in countries that are economically more developed, the disorder's presentation has raised issues regarding the extent to which such patients may nevertheless show subclinical target organ involvement, who should be recommended for parathyroid surgery, and who can be safely followed without surgical intervention, as well as questions regarding the role of medical therapy. Questions about the natural history and pathophysiology of the disorder continue to be of great interest. Inasmuch as this disorder continues to evolve, it is clear that additional careful studies are required continually to gain new insights into this disease.

INTRODUCTION AND HISTORY

Hypercalcemia is a frequent complication of cancer and has been estimated to occur in up to 20% to 30% of patients during the course of their malignant disease.[1] The incidence of hypercalcemia depends on the tumor type, with higher rates in patients with nonsmall cell lung cancer, breast cancer, and multiple myeloma, and lower rates in squamous head and neck cancers, urothelial carcinomas, and ovarian cancers. However, hypercalcemia has been reported in almost all tumor types.[2] Rates of hypercalcemia may be decreasing over time owing to the overall better therapy for cancers of all types, as well as the prophylactic use of bisphosphonates or the receptor activator of nuclear factor kappa B ligand (RANKL) inhibitor denosumab to prevent skeletal-related events, including hypercalcemia, in patients with bone metastases. For instance, recent retrospective studies using national electronic medical record databases have reported an incidence of malignancy-associated hypercalcemia (MAHC) between 2% and 3% in US cancer patients.[3,4] MAHC generally predicts a poor prognosis, and this has not changed substantially over time. Older studies had estimated that patients with this disorder have a 30-day mortality rate of 50%.[2] More recent series have suggested that hypercalcemia is associated with a median survival of 25 to 52 days, although patients with hematologic malignancies or breast cancer appeared to survive longer than those with other solid tumor types.[5-7] These data demonstrate that hypercalcemia remains a late-stage complication of most tumors.

MAHC was initially recognized in the 1920s, soon after the development of methods to measure blood calcium levels.[8] In 1936, the first series of cases was published on patients with MAHC.[9] The reported patients suffered from myeloma and breast cancer with skeletal involvement, and their hypercalcemia was attributed to skeletal destruction caused by local tumor invasion. In 1941, Fuller Albright suggested an alternative mechanism: that a circulating humoral factor might cause some cases of MAHC.[10] Studies published in the 1950s and 1960s supported this hypothesis by describing patients with hypercalcemia who lacked bony metastases.[11,12] These patients had squamous, renal, and genitourinary cancers, as opposed to breast cancer or myeloma. Lafferty concluded that these tumors must secrete parathyroid hormone (PTH) and named this process *pseudohyperparathyroidism*.[13] At that point, it was thought that tumors could cause hypercalcemia through direct skeletal involvement or by acting on the skeleton in a humoral fashion. We now refer to these conditions as two subtypes of MAHC: the first is local osteolytic hypercalcemia (LOH), and the second is humoral hypercalcemia of malignancy (HHM).[14,15]

In the 1980s, investigators made great strides in understanding the pathophysiology of both LOC and HHM. First, it was appreciated that tumor cells could make cytokines that stimulated the local production and activity of bone-resorbing osteoclasts within the bone microenvironment surrounding tumor cells. Second, investigations into HHM led to the discovery of a new hormone, PTH-related peptide (PTHrP), which is evolutionarily related to PTH and uses the same receptor. As a result, when tumors secrete PTHrP into the circulation, it acts like PTH to increase osteoclast differentiation and activity throughout the skeleton. It has also become clear that two additional types of MAHC exist: 1,25-dihydroxyvitamin D–induced hypercalcemia in patients with lymphomas, and true ectopic production of PTH. These will be discussed further later in this chapter.

KEY POINTS

- Hypercalcemia is a common complication of malignancy that occurs with all known tumor types and usually portends a poor prognosis.

NORMAL PHYSIOLOGY OF CALCIUM METABOLISM

Calcium can be found in the body in two predominant forms. First, 99% of body calcium is found in bone hydroxyapatite, which provides structural integrity to the skeleton. Second, approximately 1% of body calcium is found as soluble calcium ions in the extracellular fluid (ECF) and cytosol, which contributes to a series of diverse cellular functions.[16] Skeletal and ECF calcium are exchangeable, allowing bone to provide calcium to the ECF when calcium concentrations are low and also to store excess calcium when needed. Ionized, or free, calcium represents approximately 50% of the circulating pool, and the remaining fraction is bound to serum proteins. The ionized fraction is the physiologically important one, but it is difficult to measure, as it requires anaerobic conditions for collection and handling. Therefore, total serum calcium is most commonly used as an indirect measurement of the ionized fraction, although some medical centers now routinely measure the ionized fraction. If measuring total calcium only, correction for the patient's albumin should be made as needed.

The parathyroid glands, kidneys, skeleton, and gut are the organs involved in calcium homeostasis and their interactions are coordinated through the actions of calcium, itself, PTH, vitamin D, and PTHrP. These interactions will be described in the following sections.

Parathyroid Hormone and the Calcium-Sensing Receptor

PTH is produced from the four parathyroid glands located near the upper and lower poles of the thyroid gland. It is an 84–amino acid protein with a very short half-life (minutes) in the circulation and is degraded by the liver and kidney. PTH secretion is regulated by extracellular ionized calcium concentrations, and small changes in ionized calcium concentrations are detected by parathyroid cells through the actions of a G-protein–coupled-receptor known as the calcium-sensing receptor (CaSR).[17-23] Calcium binds to the CaSR and activates a downstream signaling cascade that suppresses PTH synthesis and subsequent secretion.[19,20,24] Persistently elevated calcium levels can result in degradation of PTH within parathyroid cells.[25] The CaSR is also expressed in the kidney, where it regulates calcium handling by the renal tubules. Hypercalcemia activates the CaSR, resulting in suppression of renal calcium reabsorption and excretion of excess calcium in the urine.[26]

The actions of PTH are mediated through a different G-protein–coupled-receptor known as the type 1 PTH/PTHrP receptor (PTH1R), because it responds to both PTH and PTHrP. Activation of the receptor by PTH initiates several signaling cascades, but the best documented has been the adenylyl cyclase pathway. In the kidney, PTH acts on proximal tubular cells to inhibit reabsorption of phosphate through removal and degradation of the sodium-phosphate cotransporters 2a and 2c from the luminal membranes.[27] It also stimulates the activity of renal 25-hydroxyvitamin D 1-alpha-hydroxylase (CYP27B1) in proximal tubular cells and inhibits 24-hydroxylase (CYP24A1), which results in an increase in the biologically active 1,25-dihydroxyvitamin D.[28] PTH increases the reabsorption of calcium from the glomerular filtrate in the kidney by increasing the positive charges on the luminal side of the tubule in the cortical thick ascending loop of Henle and by regulating the trafficking of calcium channels into the apical membrane of cells in the distal tubule.[29] In the skeleton, PTH activates bone turnover and releases stored calcium. It does this by stimulating transport of calcium across bone lining cells from a pool of calcium at the surface of bone. It also stimulates both bone resorption and bone formation. PTH increases the number and activity of bone-forming osteoblasts and bone-resorbing osteoclasts, increases the size of the osteoblast precursor pool,[30] increases the bone-forming activity of mature osteoblasts, and promotes the release of colony-stimulating factor 1 and RANKL, which stimulate the formation of new osteoclasts and activate mature osteoclasts.[31] PTH inhibits osteoblast production of osteoprotegerin, which is a soluble decoy receptor for RANKL that inhibits osteoclast development. The ultimate effects of PTH on bone turnover depend on the pattern of PTH exposure. Continued long-term elevations in PTH stimulate net bone resorption, while intermittent PTH stimulation can result in net bone formation. See Chapter 47 for further discussion on PTH.

Vitamin D

In the skin, keratinocytes absorb ultraviolet light and convert 7-dehydrocholesterol to vitamin D3.[32] This biologically inert form of vitamin D is then hydroxylated in the liver by vitamin D 25-hydroxylase (CYP2R1) to 25-hydroxyvitamin D3.[33] The second hydroxylation occurs in the kidney by CYP27B1 to convert 25-hydroxyvitamin D3 to 1,25-dihydroxyvitamin D3.[33] This enzymatic process in the kidney is stimulated by PTH and phosphate and inhibited by hypercalcemia and FGF23. CYP27B1 is also expressed in immune cells, especially activated macrophages. Therefore, 1,25-dihydroxyvitamin D3 can be produced by macrophages, classically in granulomas.

Vitamin D is a steroid hormone that interacts with nuclear receptors to regulate gene expression. When 1,25-dihydroxyvitamin D is present, the vitamin D receptor (VDR) heterodimerizes with the retinoid acid X receptor and binds to specific DNA sequences within the target gene.[34,35] 1,25-dihydroxyvitamin D stimulates calcium absorption from the diet by upregulating expression of the components of the transport mechanism by which calcium is transferred across enterocytes from the lumen into the ECF.[35] At pathologic levels, 1,25 dihydroxyvitamin D can increase bone resorption by binding to the VDR on osteoblasts and stimulating osteoblastic production of RANKL, leading to osteoclast activation and bone resorption.[36,37] See Chapter 50 for a detailed discussion of vitamin D chemistry and biology.

Parathyroid Hormone–Related Protein

PTHrP is a "cousin" of PTH; both peptides are derived from related genes that, together with *TIP-39*, define a small gene family. PTHrP was initially identified as a cause of MAHC. Much research has now shown that PTHrP is a widely expressed cytokine that is involved in a variety of physiologic functions. PTHrP is discussed at greater length in Chapter 48. What follows here is a short discussion enabling the reader to appreciate its pathophysiologic role in HHM.

In humans, PTHrP is encoded by a single-copy gene containing eight exons and at least three promoters located on the short arm of chromosome 12.[38-40] Many different hormones and growth factors regulate the transcription and/or stability of PTHrP mRNA. As with PTH, the CaSR has been found to regulate PTHrP gene expression in many cells.[20,41]

The amino terminus of PTHrP is remarkably similar to that of PTH. The two peptides share eight of the first 13 amino acids and a high degree of predicted secondary structure over the next 21 amino acids. These common sequences allow both proteins to bind and activate PTH1R. The vast majority of studies *in vitro* suggest that this receptor binds PTHrP and PTH with equal affinity, and that both activate the receptor in an identical manner. However, the human PTH1R may respond slightly differently to PTH and PTHrP. There appear to be physical differences in the binding of the two peptides to different conformational states of the receptor, so that the duration of cyclic adenosine monophosphate (cAMP) production is shorter for PTHrP(1–36) than for PTH(1–34).[42] Nevertheless, when PTHrP enters the systemic circulation, it can mimic the effects of PTH and cause hypercalcemia in HHM.[15]

PTHrP has been found in at least some cells of almost all organs, and a variety of functions have been ascribed to PTHrP. These are discussed at greater length in Chapter 48. Pertinent to its role in causing hypercalcemia in cancer, it is worth highlighting PTHrP's function during lactation. Secreting milk increases maternal calcium requirements, and a significant portion of the calcium used for milk production comes from the mother's skeleton. As a result, lactating women lose 5% to 8% of their bone mass over the first 6 months of full-time nursing, and lactating rodents can lose 25% to 30% of their skeletal mass in as little as 12 to 14 days.[43] Bone loss during this time is mediated, in part, by the secretion of PTHrP from breast epithelial cells into the systemic circulation. This is the only time that PTHrP circulates in normal individuals in appreciable amounts, and its physiologic function is to increase bone resorption to liberate skeletal calcium stores for milk production. This PTH-like function during reproductive cycles is an important evolutionary pressure that helped to maintain PTHrP's ability to share the same receptor with PTH, even though, in every other aspect, the two peptides function much differently. Given that HHM exists because PTHrP and PTH share the same receptor, ultimately this evolutionary pressure also helps to explain why hypercalcemia occurs in many malignancies.[44]

KEY POINTS

- Calcium regulation involves intricate interactions between ionized calcium levels, parathyroid hormone (PTH), vitamin D, and bone cells that regulate calcium release from bones. PTH-related peptide (PTHrP) is a local growth factor that shares homology with PTH and that can activate the same PTH/PTHrP receptors that PTH uses to regulate calcium metabolism. As a result, excess production of PTHrP by cancer cells can activate PTH/PTHrP receptors in bone and kidney to cause hypercalcemia.

MALIGNANCY-ASSOCIATED HYPERCALCEMIA

Historically, MAHC has been subdivided into two main categories. The first occurs in patients with few or no bone metastases but with diffuse upregulation of bone resorption. These tumors produce a humoral factor(s) (usually PTHrP) that circulates and causes increased osteoclast numbers and activity. This type of MAHC has been referred to as *HHM*. The second main category includes tumors with osteolytic bone metastases referred to as *LOH*. In these tumors, the metastatic cells within the skeleton produce local paracrine factors that increase osteoclastic bone resorption around the tumor deposits, but not systemically. These tumors require an extensive skeletal tumor burden to cause hypercalcemia. Two additional, although less common, subtypes of MAHC have been described: 1,25-dihydroxyvitamin D induced hypercalcemia in patients with lymphoma and some solid tumors, and ectopic hyperparathyroidism produced by nonparathyroid tumors.

Humoral Hypercalcemia of Malignancy

HHM has been considered to be the more common type of MAHC, representing 75% to 80% of cases in consecutive series of patients with MAHC.[14,15] However, two more recent retrospective studies examining elevated PTHrP levels have suggested that HHM represents only 32% to 38% of MAHC.[45,46] In contrast, other recent studies of MAHC suggested that 57% to 74% of cases had HHM based on the absence of bone metastases.[7,47] It is not clear whether these different estimates reflect different patient populations or differences in patient identification and/or the sensitivity of PTHrP measurements. Classically, HHM occurs most commonly in squamous, renal, and genitourinary malignancies, some breast cancers, and human T-cell leukemia virus 1–associated adult T-cell leukemia/lymphomas.[48] However, almost all tumor types have been reported to occasionally cause HHM. It is difficult to determine the exact incidence of HHM in patients with different types of cancer, as the frequency generally increases as cancer progresses. For instance, approximately 15% of patients with renal cell carcinoma were shown to have hypercalcemia before treatment.[49] In contrast, up to 50% of patients with squamous cell tumors of the head and neck followed for several years eventually developed HHM.[50] In fact, hypercalcemia is typically a complication of advanced cancer, and the prognosis is poor in patients with HHM, with reports suggesting a median survival of 1 to 3 months.[51,52]

HHM is most commonly caused by a tumor, distant from the skeleton, releasing PTHrP into the systemic circulation. PTHrP is often a normal product of the cells of origin of the tumor, but in the setting of malignancy PTHrP production is upregulated by tumor cells, and the tumors evade the normal barriers that usually keep PTHrP within the local tissue environment. As a result, PTHrP enters the systemic circulation and gains access to the PTHR1 pool in the skeleton and kidney that is normally stimulated by PTH. This is associated with a characteristic pattern of biochemical abnormalities first defined by Stewart and colleagues in 1980.[15] Patients typically demonstrate elevated serum calcium levels associated with suppressed PTH levels and low 1,25-dihydroxyvitamin D levels. As a result, calcium clearance in the kidneys is increased, and gut calcium absorption is decreased, contributing to a profound negative calcium balance. Serum phosphorus levels are low-normal or low, with a decreased renal tubular reabsorption of phosphate. Nephrogenous cAMP (NcAMP) excretion rates are elevated, reflecting activation of the renal proximal tubular PTH receptor despite the reduction in circulating PTH levels. The elevated NcAMP levels in HHM formed the basis for biochemical assays that resulted in the purification of PTHrP from tumors and the cloning of the *PTHrP* gene in the 1980s.[15]

Hypercalcemia in HHM is caused by the release of calcium from the skeleton at a rate that exceeds the kidney's ability to excrete the excess load (Fig. 55.1). Patients initially develop hypercalciuria but eventually develop dehydration owing to an osmotic diuresis combined with the effects of calcium to activate the CaSR in the distal tubule and collecting duct of the kidney, which, in turn, inhibits aquaporin trafficking and induces a form of nephrogenic diabetes insipidus. Once patients become dehydrated, serum calcium levels typically rise rapidly, and patients develop symptoms of lethargy, anorexia, and confusion from the elevated ionized calcium levels that only worsen the dehydration and accelerate the increase in serum calcium levels.

Although PTH and PTHrP act on the same receptor, it was originally reported that several biochemical aspects of HHM differed from changes typical of primary hyperparathyroidism. First, as noted earlier, renal calcium clearance was higher in HHM than that observed in hyperparathyroidism. Second, although PTHrP levels are elevated in HHM, 1,25-dihydroxyvitamin D levels were described to be low. By contrast, the elevations in PTH in primary hyperparathyroidism were accompanied by increased 1,25-dihydroxyvitamin D levels. Finally, bone histomorphometry studies in patients with HHM demonstrated very elevated rates of bone resorption but suppressed bone formation rates.[53] Typically, in primary hyperparathyroidism, rates of both bone formation and bone resorption are elevated. Similar differences in bone formation rates in HHM as compared with hyperparathyroidism are noted when biochemical markers of bone turnover such as total deoxypyridinoline, pyridinoline cross-linked carboxyterminal telopeptide of type 1 collagen, serum osteocalcin, and serum bone type alkaline phosphatase were measured.[54] It is still not entirely clear why elevations in PTHrP produce different effects on the kidney and bone cells if both peptides act on the same receptor. In addition, more recent studies have suggested that some patients with HHM have elevated levels of both PTHrP and 1,25-dihydroxyvitamin D (discussed later). Studies by Horwitz and colleagues revealed that infusions of PTHrP in normal human subjects are less effective at stimulating 1,25-dihydroxyvitamin D production than are infusions of PTH.[55-57] As for the uncoupling of bone formation from bone resorption, tumor production of IL-6 has been implicated in human squamous carcinoma cells that also secrete PTHrP, and this cytokine may accelerate osteoclastic bone resorption and suppress osteoblastic function.[58] Finally, although PTHrP and PTH appear to act equivalently in many experimental systems, there are differences in the way they bind to the PTH1R, providing a potential mechanism through which the two proteins may have tissue-specific differences in signaling that would explain divergent effects on 1,25-dihydroxyvitamin D production and the stimulation of bone formation by osteoblasts.[15,42,59,60]

Fig. 55.1 Comparison of normal calcium fluxes with malignancy-associated hypercalcemia. **A,** The central box represents extracellular fluid (*ECF*), which contains approximately 1000 mg of calcium (*Ca*). This compartment interfaces with the gastrointestinal (*GI*) tract, the kidney, and the skeleton. The fluxes into and out of the ECF are measured in mg/d. There is a zero calcium balance under homeostatic conditions. **B,** In humoral hypercalcemia of malignancy, elevated circulating parathyroid hormone (*PTH*)–related protein (*PTHrP*) levels result in an uncoupling of bone resorption from bone formation and a net output of calcium from bone. There is decreased intestinal absorption of calcium secondary to reduced 1,25-dihydroxyvitamin D levels. The kidney filters an increased load of calcium, and PTHrP acts on the kidney to enhance renal retention of calcium. However, this is insufficient to reduce serum calcium concentrations to normal levels.**C,** In local osteolytic hypercalcemia, local release of factors from skeletal metastases leads to the local uncoupling of bone resorption from formation. If there are enough metastases, there is a net output of calcium from bone. There is decreased intestinal absorption of calcium secondary to reduced 1,25-dihydroxyvitamin D levels. The kidney filters an increased load of calcium, but this is insufficient to reduce serum calcium concentrations to normal levels. **D,** In 1,25-dihydroxyvitamin D–mediated hypercalcemia, there is a marked increase in intestinal calcium absorption, and there also may be an increase in bone resorption. The kidney filters an increased load of calcium, but this is insufficient to reduce serum calcium concentrations to normal levels. (**A,** Modified from Stewart AF. Normal physiology of bone and mineral homeostasis. In Andreoli TE, et al, eds. *Andreoli and Carpenter's Cecil essentials of medicine.* Philadelphia: Elsevier Saunders; 2010.)

Local Osteolytic Hypercalcemia

LOH is a second major type of MAHC, comprising approximately 20% to 30% of patients in consecutive series of patients with MAHC.[14,15,61] In patients with LOH, the hypercalcemia is caused by tumor growth within bone, which leads to the stimulation of osteolysis around the metastatic cancer cells with release of calcium into the systemic circulation. To develop hypercalcemia, patients must have extensive skeletal metastases. Classically, the most common tumors presenting with this syndrome include myeloma, breast cancer, and lymphoma.

The biochemical findings in LOH include hypercalcemia with reduced PTH and 1,25-dihydroxyvitamin D levels, similar to HHM. However, in this condition patients have normal serum phosphate concentrations and a normal renal phosphate threshold. In contrast to HHM, PTHrP levels are undetectable, so NcAMP levels are reduced secondary to the suppressed PTH levels. Urinary calcium excretion is increased as a result of an increased filtered load of calcium found in hypercalcemic conditions and a decreased distal tubular calcium reabsorption in the setting of lower PTH levels. Intestinal absorption of calcium is also reduced because of the decreased circulating 1,25-dihydroxyvitamin D levels. As with HHM, this results in a net negative calcium balance.

The pathophysiology of LOH is an extension of the pathophysiology of osteolytic bone metastases.[62,63] In order for tumor cells to survive and grow in bone, they influence the behavior of normal bone cells to remodel the bone microenvironment, often activating bone resorption and causing osteolysis. This leads to the release of factors from the bone matrix that, in turn, stimulate further growth of the tumor cells, causing more osteolysis. This vicious cycle of peritumor osteolysis and tumor growth has been the focus of many studies. In short, it appears that tumor cells produce soluble factors that lead to increased osteoclast recruitment, differentiation, and activity.[64-67] Some tumors also elaborate factors that inhibit osteoblast-mediated bone formation. As a result, the tumors cause progressive bone destruction, allowing them to expand within the skeleton. If the number and size of the osteolytic metastases is great enough, then the release of calcium from the skeleton will exceed the kidney's ability to excrete the filtered load, and patients will develop clinical hypercalcemia, usually associated with renal insufficiency (see Fig. 55.1). As opposed to HHM, bone resorption does not happen throughout the skeleton in LOH, just around the individual tumor deposits. The general pathophysiology of bone metastases has been reviewed in great detail previously. In this setting, we will only briefly review some of the main cytokines that have been implicated in driving the vicious cycle of osteolysis, but the reader is referred to other reviews for a more complete discussion of this topic.[68-70]

One of the tumors that frequently causes extensive bone destruction and hypercalcemia is myeloma. In 1974, Mundy described an osteoclast-activating factor that was produced by myeloma cells.[71] Many subsequent studies have identified a series of cytokines produced by myeloma cells that have the ability to cause osteolysis. These include interleukin (IL)-1α, IL-1β, tumor necrosis factor (TNF)-α, TNF-β (lymphotoxin), transforming growth factor (TGF)-α, macrophage inflammatory protein-1α, IL-3, IL-6, IL-17, and CD-47.[71] Many of these cytokines increase osteoclast differentiation and activity by increasing the production of RANKL by osteoblasts.[72-74] RANKL is the dominant factor produced by osteoblasts to regulate the production and activity of osteoclasts, and this factor acts through a receptor, receptor activator of nuclear factor kappa B (RANK), found on osteoclast progenitors and mature osteoclasts. Recently, direct interactions of myeloma cells with osteocytes and bone marrow stromal cells have been shown to be important for the upregulation of the above cytokines and increased RANKL production or decreased secretion of the RANKL inhibitor, osteoprotegerin (OPG).[75] An important mediator of these direct interactions appears to be activation of Notch signaling pathways. It has also become clear that suppression of bone formation contributes significantly to the pathogenesis of myeloma bone disease. This appears to be related to the secretion of Dickkopf-1, an inhibitor of the Wnt signaling pathway, by myeloma cells. In addition, myeloma bone disease is associated with increased production of sclerostin, a dual Wnt/bone morphogenic protein inhibitor that is made by osteocytes. Inhibition of Wnt signaling suppresses osteoblast activity and bone formation, augmenting the local osteolysis and release of calcium from the bone.[76-78]

Breast cancer is the second tumor type classically associated with LOH. Bone metastases are common in breast cancer, occurring in up to 70% of patients with advanced disease.[62,63] As in myeloma, bone metastases from breast cancers are typically osteolytic, and if the skeletal burden is great enough, a significant level of calcium can be released from the skeleton to overwhelm the body's adaptive mechanisms, resulting in hypercalcemia. It is difficult to ascertain the current incidence of hypercalcemia in patients with breast cancer and bone metastases. Older studies suggested that 10% to 15% of all patients with breast cancer developed hypercalcemia, the majority of whom had bone metastases.[79] More recent studies (usually drug trials) group together hypercalcemia, pathologic fracture, radiation treatment for impending fracture, and bone pain under the term *skeletal-related events* (*SREs*) and do not often report the incidence of hypercalcemia separately. In these trials, the control group of patients with bone

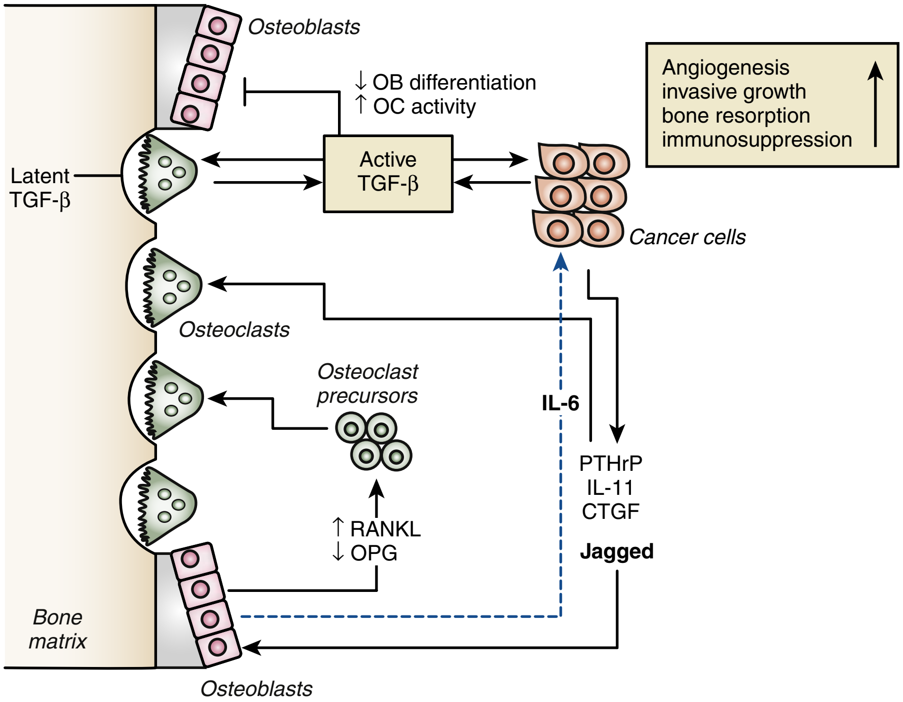

Fig. 55.2 Osteolytic bone metastasis in breast cancer. In skeletal metastases, the tumor cells make factors, including parathyroid hormone–related peptide (*PTHrP*), that upregulate osteoclastic bone resorption. This results in the release of transforming growth factor (*TGF*)-β from the bone matrix, which acts on cancer cells to further stimulate the production of osteolytic factors, such as PTHrP, connective tissue growth factor (*CTGF*), interleukin (IL)-6, and IL-11. These factors increase the receptor activator of nuclear factor kappa B ligand (RANKL)/ osteoprotegerin (*OPG*) expression ratio in bone stromal cells such as osteoblasts, resulting in osteoclastogenesis. Moreover, active TGF-β stimulates Jagged 1 expression in cancer cells, which in turn stimulates Notch signaling in osteoclasts (*OC*) and osteoblasts (*OB*), resulting in increased osteoclastogenesis and production of the cytokine IL-6 by osteoblasts (*blue dotted line*), which stimulates proliferation of tumor cells. TGF-β also inhibits osteoblast differentiation. Thus, once osteolysis is established, a vicious cycle of bone resorption and tumor cell proliferation is fed by the release of growth factors from bone matrix, tumor cells, and bone cells. (Reproduced with permission from Buijs JT, Stayrook KR, Guise TA. The role of TGF-beta in bone metastasis: novel therapeutic perspectives. *Bonekey Rep*. 2012;1:96.)

metastases had an SRE rate of approximately 60%. The use of prophylactic bisphosphonates is associated with an aggregate 15% reduction in SREs, so it is likely that the widespread use of these medications in patients with breast cancer and bone metastases has reduced the incidence of hypercalcemia by at least a similar amount.[80,81]

Like myeloma cells, breast cancer cells have been shown to produce a variety of factors that induce local bone resorption (Fig. 55.2). One of the best studied of these factors is PTHrP. It is well documented that PTHrP is produced by a number of primary breast carcinomas, and that this sometimes leads to classical HHM.[82] However, animal models have suggested that localized PTHrP production by breast tumor cells contributes to the osteolysis associated with skeletal metastases.[83,84] These studies have suggested that, in response to the bone microenvironment, breast cancer cells metastatic to the skeleton produce more PTHrP than cells in the primary tumor.[84,85] TGF-β, released at sites of bone resorption, has been shown to upregulate PTHrP production through a signaling pathway involving the transcription factor Gli2.[86] PTHrP, in turn, increases the production of RANKL and decreases the production of OPG, increasing osteoclast numbers and activity.[85] This sets up a feedforward loop between PTHrP production and bone resorption, contributing to a vicious cycle of osteolysis. In addition, unlike in normal breast cells, CaSR signaling in breast cancer cells stimulates PTHrP production and can synergize with the effects of TGF-β.[87,88] Finally, the mechanical stiffness of bone tissue may also increase PTHrP production.[89] Thus, several aspects of the bone microenvironment conspire to increase PTHrP production in skeletal metastases. However, PTHrP is not the only factor important in this process. Breast cancer cells have been shown to produce other osteolytic factors, such as IL-6, IL-8, IL-11, prostaglandin E2, Jagged 1, macrophage colony-stimulating factor (MCSF), and macrophage-stimulating protein (MSP).[66] MCSF and MSP may act directly to stimulate osteoclast production and activity, while the other factors act with PTHrP to stimulate RANKL production by osteoblasts.[66,90,91] As depicted in Fig. 55.2, the growth of osteolytic metastases depends on a vicious cycle of bone resorption and tumor cell proliferation that is fed by the release of growth factors from the bone matrix, the breast cancer cells, and normal bone cells.[62]

Overproduction of 1,25-Dihydroxyvitamin D

Another less common cause of MAHC is the overproduction of 1,25-dihydroxyvitamin D by lymphomas, both Hodgkin and non-Hodgkin types.[92-96] In this setting, local activation of CYP27B1 activity within or around the tumor results in the overproduction of the active form of vitamin D. In at least one carefully studied patient, the source of the CYB27B1 was the tumor-associated macrophages and not the lymphoma cells themselves.[97] This would suggest that the tumor cells make some paracrine factor that upregulates CYP27B1 expression in macrophages, although it is not clear whether lymphoma cells can also sometimes express CYB27B1. Unlike the kidney, there is no systemic feedback inhibition of the tumor-associated CYB27B1 activity, but 1,25-dihydroxyvitamin D production is responsive to 25-hydroxyvitamin D_3 levels. Hypercalcemia in these patients is largely secondary to the hyperabsorption of calcium in the intestine, although high 1,25-dihydroxyvitamin D levels can also directly cause bone resorption (see Fig. 55.1). Patients typically have normal serum phosphate levels and increased renal calcium excretion. PTH levels are appropriately suppressed in the face of hypercalcemia, and PTHrP concentrations are unmeasurable.[96]

Some solid tumors also cause hypercalcemia associated with elevated levels of 1,25-dihydroxyvitamin D, suppressed PTH levels, and low PTHrP levels. This has most commonly been reported in patients with seminomas or dysgerminomas, but also in a patient with small-cell cervical cancer.[98-101] While the majority of the reports have been single cases, Evans and colleagues examined a series of 12 dysgerminomas and documented increased expression of CYP27B1 in tumor cells and associated macrophages at both the mRNA and protein levels.[98] In addition, some cases of MAHC appear to be related to overproduction of both 1,25-dihydroxyvitamin D and PTHrP in the same patient. The cooccurrence of elevated levels of both hormones in MAHC has been reported in ovarian carcinoma, renal cell carcinoma, seminoma, adult T-cell leukemia/lymphoma, and pancreatic neuroendocrine tumors.[102-107] The authors have also recently seen similar patients with aggressive urothelial carcinoma and breast cancer at Yale New Haven Hospital. It is not clear whether the production of 1,25-dihydroxyvitamin D is occurring from the tumor itself as in lymphomas, or by tumor-associated macrophages or from the kidney. However, in one instructive case report of an ovarian clear cell adenocarcinoma, venous sampling at the time of resection demonstrated that the tumor produced PTHrP but not 1,25-dihydroxyvitamin D.[108] Nonetheless, both PTHrP and 1,25-dihydroxyvitamin D levels were normalized after surgery, suggesting that PTHrP or some other tumor product led to increased 1,25-dihydroxyvitamin D production by the kidney. In fact, despite the original descriptions of low 1,25-dihydroxyvitamin D levels in HHM, the cooccurrence of elevated PTHrP and 1,25-dihydroxyvitamin D levels may not be that unusual. In a recently published retrospective examination of 101 patients with MAHC from Memorial Sloan Kettering Cancer Center, 34 patients had simultaneous elevations of both PTHrP and 1,25-dihydroxyvitamin D. In addition, these patients were significantly more likely to have an incomplete response to antiresorptive therapy than patients with normal 1,25-dihydroxyvitamin D levels.[109] Thus, it is still important to measure 1,25-dihydroxyvitamin D levels in all patients with MAHC, as elevated levels may have therapeutic implications.

Ectopic Production of Parathyroid Hormone

Although HHM was originally thought to be secondary to ectopic PTH production, it is quite rare that MAHC is actually caused by ectopic production of PTH. Approximately 20 cases exist in the literature of ectopic hyperparathyroidism caused by a nonparathyroid tumor. These tumors include neuroendocrine tumors, hepatocellular carcinoma, medullary thyroid cancer, ovarian carcinoma, small-cell lung carcinoma, squamous carcinoma, rhabdoid tumor of the kidney, endometrial adenosquamous carcinoma, and thymoma.[59,110-126] Immunoradiometric two-site assays for intact PTH and PTHrP allow for the determination as to whether PTH or PTHrP is causing hypercalcemia in malignancy. There is no crossreactivity between PTH and PTHrP in these assays.[120] Nussbaum and coworkers described a patient with ovarian carcinoma, in which genetic evaluation of the tumor cells revealed DNA amplification and rearrangement in the upstream regulatory region of the *PTH* gene. This resulted in increased PTH expression.[120] VanHouten and associates described a patient with a high-grade neuroendocrine carcinoma of the pancreas found to have ectopic PTH production. Genetic evaluation of these tumor cells revealed transactivation of the PTH gene promoter associated with hypomethylation of the *PTH* gene locus, indicative of reactivation of *PTH* gene transcription in the tumor cells.[125]

KEY POINTS

- Bone resorption is the key pathophysiologic mechanism by which excess calcium is released into the circulation in malignancy-associated hypercalcemia (MAHC). The four main mechanisms underlying MAHC are: (1) elevation in circulating parathyroid hormone–related protein secreted by tumors outside the skeleton, known as humoral hypercalcemia of malignancy (HHM), (2) local cytokine production by tumor cells located within the bone microenvironment, known as local osteolytic hypercalcemia (LOH), (3) overproduction of 1,25-dihydroxyvitamin D, and (4) ectopic production of parathyroid hormone.

TREATMENT

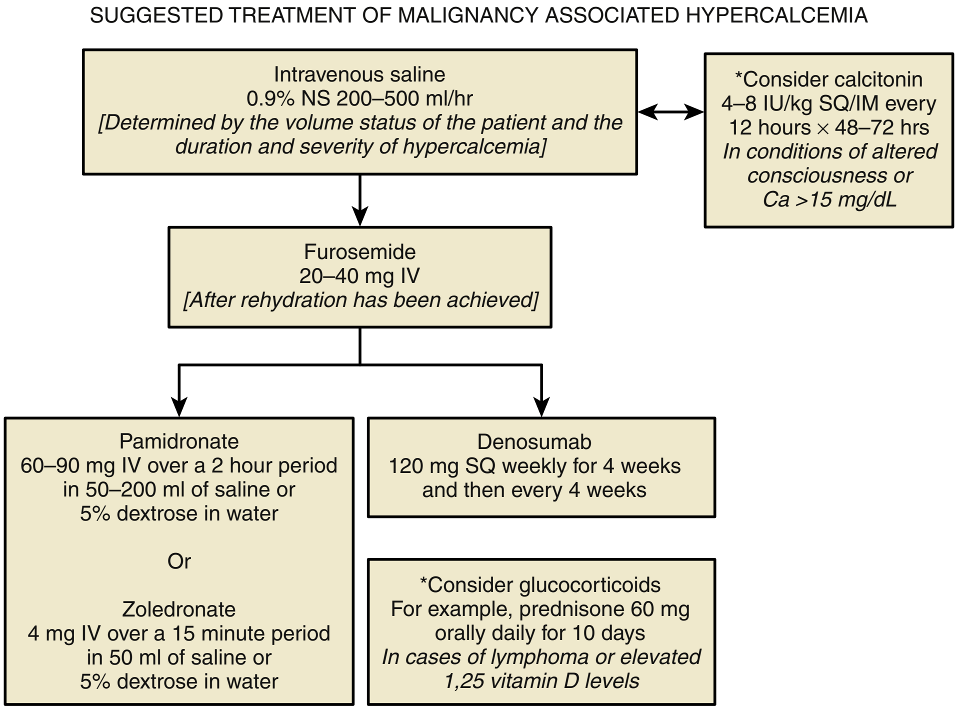
Hydration

Hypercalcemia is associated with polyuria. In addition, hypercalcemic patients also suffer from reduced oral intake because of anorexia, nausea, and vomiting. These factors lead to dehydration and a reduction in glomerular filtration rate.[127] An impairment in renal function, in turn, limits the ability to excrete the increased calcium load coming from bone and accelerates the development of hypercalcemia. As a result, the first goal of therapy is to correct volume depletion (Fig. 55.3). The initial rate and duration of fluid administration should be determined by clinical signs of dehydration, the duration and severity of hypercalcemia, and underlying medical conditions, especially cardiovascular disease. It has typically been recommended to hydrate patients with 0.9% sodium chloride solution (also known as normal saline), initially with a 1- to 2-liter bolus followed by continuous infusion at 200 to 500 mL/hour intravenously, titrating to a urine output of 100 to 150 mL/hour.[128,129] After initial volume repletion and establishment of adequate urine output, fluids can be continued at greater than 100 mL/hour, but it is important to carefully monitor vital signs and watch for signs of fluid overload, especially in cases with existing comorbidities such as congestive heart failure.[127,130] Although intravenous fluid administration can transiently lower serum calcium concentrations on the order of 1 to 1.5 mg/dL, additional therapies are required to lower calcium further and to maintain the lower calcium levels.

It has been common practice to add loop diuretics, such as furosemide at a dose of 20 to 40 mg intravenously, after rehydration has been achieved to promote calcium excretion through a forced saline diuresis. The concept is to take advantage of the fact that sodium delivery to the distal tubule promotes urinary calcium excretion and helps to accelerate calcium clearance by the kidneys.[1,127] However, LeGrand and colleagues reviewed the literature on this topic and argued that routine use of loop diuretics in the treatment of MAHC was not helpful.[131] Clearly, if loop diuretics are given before adequate volume repletion, they run the risk of prolonging dehydration and may actually impair the excretion of a calcium load on this basis. Therefore, if diuretics are to be used, their administration must be delayed until volume status has been fully restored. In addition, they are valuable in managing hypercalcemic patients who develop fluid overload after aggressive fluid resuscitation.[131]

Inhibition of Bone Resorption

The majority of patients with MAHC are hypercalcemic because of excessive bone resorption. Therefore, the mainstay of therapy is the administration of powerful antiresorptive agents, primarily



SUGGESTED TREATMENT OF MALIGNANCY ASSOCIATED HYPERCALCEMIA
Intravenous saline
0.9% NS 200–500 ml/hr
[Determined by the volume status of the patient and the duration and severity of hypercalcemia]
*Consider calcitonin
4–8 IU/kg SQ/IM every 12 hours × 48–72 hrs
In conditions of altered consciousness or Ca >15 mg/dL
Furosemide
20–40 mg IV
[After rehydration has been achieved]
Pamidronate
60–90 mg IV over a 2 hour period in 50–200 ml of saline or 5% dextrose in water
Or
Zoledronate
4 mg IV over a 15 minute period in 50 ml of saline or 5% dextrose in water
Denosumab
120 mg SQ weekly for 4 weeks and then every 4 weeks
*Consider glucocorticoids
For example, prednisone 60 mg orally daily for 10 days
In cases of lymphoma or elevated 1,25 vitamin D levels

Fig. 55.3 Suggested treatment for malignancy-associated hypercalcemia. *NS,* Normal saline; *IV,* intravenous; *SQ,* subcutaneous; *IM,* intramuscular.

bisphosphonates and denosumab. However, other agents, such as calcitonin, gallium nitrate, and mithramycin, have also been described to be helpful in lowering calcium levels. In the sections that follow, we will discuss the available agents for inhibiting bone resorption, concentrating on the most clinically useful and available agents.

Calcitonin. Calcitonin is a peptide hormone secreted by the parafollicular cells of the thyroid gland that acts to inhibit osteoclast activity. It has been used as an antiresorptive therapy for both hypercalcemia of malignancy and Paget disease.[127,130] It also has been shown to decrease the renal tubular resorption of calcium, thus promoting renal calcium excretion.[132,133] The benefit of calcitonin is its rapid onset of action, but its limitations are a short period of effectiveness and its relatively modest calcium-lowering actions. Salmon calcitonin has a longer half-life in the circulation than human calcitonin, and it is given as a subcutaneous or intramuscular injection at a dose of 4 to 8 IU per kilogram every 8 to 12 hours.[1] Administration of calcitonin results in a rapid reduction in serum calcium concentrations with a maximal response within 12 to 24 hours. However, the reductions are small (approximately 1 mg/dL), and the effects are usually lost within 48 to 96 hours, probably because of the downregulation of calcitonin receptors.[134] Nevertheless, it can be a valuable bridging agent that can rapidly lower calcium levels acutely while waiting for the more prolonged onset of other antiresorptive agents. This can be an important initial therapy for patients with extreme elevations in serum calcium levels. Side effects most commonly experienced with calcitonin include nausea, vomiting, and pain or irritation at the injection site.[127]

Bisphosphonates. Bisphosphonates are the most commonly used medications to treat MAHC in the United States. These drugs are analogs of pyrophosphates, which resist enzymatic hydrolysis and have a high affinity for hydroxyapatite.[135] Bisphosphonates concentrate at areas of high bone turnover and inhibit osteoclast function. Most patients are treated either with pamidronate (aminohydroxypropylidene bisphosphonate) or zoledronate (zoledronic acid), both potent nitrogen-containing bisphosphonates that interfere with protein prenylation through the inhibition of the mevalonate pathway enzyme, farnesyl disphosphate synthase, which is downstream of HMG-CoA reductase. These medications inhibit osteoclast function by inducing apoptosis.[135] The standard dose of pamidronate is 60 to 90 mg given intravenously over a 2-hour period in a solution of 50 to 200 mL of saline or 5% dextrose in water.[1,136] Zoledronate is given as a 4-mg intravenous infusion over 15 minutes in a solution of 50 mL of saline or 5% dextrose in water.[1] The serum calcium level normalizes in most patients, but the response can take 3 to 7 days and last from 1 to 3 weeks. In one study examining the dose-response to treatment with pamidronate in patients with MAHC, corrected serum calcium normalized in 61% of patients receiving 60 mg and 100% of patients receiving 90 mg. The mean duration of normalization in these two groups was 13.3 and 10.8 days in the 60-mg and 90-mg treatment groups, respectively.[136] Zoledronate has been shown to be superior to pamidronate in both clinical response and time to hypercalcemia relapse. One study, which was a pooled analysis from two randomized, double-blind, parallel-group trials, showed that zoledronate was more effective at normalizing serum calcium levels in patients with HCM, with a significantly longer time to relapse than pamidronate.[137,138] In this study, two treatment doses of zoledronic acid, 4 mg and 8 mg, were compared with 90 mg of pamidronate. The complete response rates were 88.4%, 86.7%, and 69.7%, respectively.[138] The corrected serum calcium normalized by day 4 in 50% of the zoledronic acid–treated patients and 33.3% of the pamidronate-treated patients.[138] The median duration of complete response was 32 and 43 days in those treated with 4 mg or 8 mg of zoledronic acid, respectively, and 18 days in those treated with pamidronate.[138]

The dosing interval of bisphosphonates to control MAHC is typically every 3 to 4 weeks, depending on the recurrence of hypercalcemia. There may be a reduction in efficacy with repeated dosing. The intravenous bisphosphonates are excreted unchanged by the kidneys and must be adjusted for impaired renal function. Zoledronate is generally contraindicated in patients with a creatinine clearance of less than 30 mL/min. The most common adverse effects are renal failure and 24 to 48 hours of transient flulike symptoms, including fever, chills, mild bone aches, and pain precipitated by the initial infusion. The fever is often mild and usually occurs only with the first infusion.

In addition to the acute treatment of MAHC, bisphosphonates are now routinely given to patients with myeloma and breast cancer to prevent the occurrence of SREs, including hypercalcemia. A comprehensive metaanalysis demonstrated that treatment of women with breast cancer and bone metastases with regular infusions of bisphosphonates reduced the overall rate of SREs by 15% in randomized trials and also delayed the onset of the first SRE.[81] However, this treatment did not prolong survival, and adjuvant treatment of breast cancer without bone metastases was not associated with enhanced survival.[139]

Denosumab. Denosumab is a humanized monoclonal antibody that binds to RANKL and prevents it from binding to the receptor RANK on osteoclast precursors and mature osteoclasts. This leads to the inhibition of the differentiation, activation, and function of osteoclasts which, in turn, leads to a reduction in bone resorption.[140] It has a profound suppressive effect on biochemical markers of bone resorption and is the most powerful antiresorptive agent currently available.[141] Denosumab is cleared through the reticuloendothelial system, independent from the kidneys.[140] The lack of renal toxicity makes it an attractive treatment option in patients with impaired renal function, who cannot tolerate bisphosphonates. Hypocalcemia is one of the main adverse effects of denosumab. Patients in osteoporosis trials also had a slightly increased incidence of skin infections as compared with patients treated with placebo, although this has not been specifically noted in cancer patients.[142]

Denosumab has been shown to prevent SREs or hypercalcemia of malignancy in phase III studies of advanced malignancies.[143-146] Administration of denosumab was associated with an 18% reduction in the risk for SREs[143] and a 70% success rate in normalization of serum calcium levels in a small study.[147] It also appears that denosumab may be useful in patients with MAHC who do not respond to bisphosphonates. In a study by Hu et al., patients with hypercalcemia of malignancy refractory to bisphosphonate treatment received subcutaneous denosumab on days 1, 8, 15, and 29, and then every 4 weeks at a dose of 120 mg given as a subcutaneous injection.[148] In this study, by day 10, 12 of 15 patients had responded with albumin-corrected serum calcium (CSC) levels less than 11.5 mg/dL, and the median duration of response was 26 days. In 10 of 15 patients, the CSC was less than 10.8 mg/dL.[148]

Glucocorticoids

Glucocorticoids can be an effective treatment for hypercalcemia associated with an overproduction of 1,25-dihydroxyvitamin D in patients with lymphoma.[127] This is likely because of the ability of glucocorticoids to suppress local cytokine production, resulting in the suppression of 1,25-dihydroxyvitamin D production through a reduction in vitamin D CYB27B1 activity.[130] As discussed previously, some patients with HHM and elevated PTHrP levels may also have elevations in 1,25-dihydroxyvitamin D, and this may predict an incomplete response to bisphosphonates.[109] Although it has not been systematically studied, it would be reasonable to consider adding steroids to the treatment of these patients as well. Treatment can consist of 60 mg/day of prednisone for 10 days.[1] This treatment can interfere with some chemotherapeutic agents, and treatment can be associated with hypokalemia, hyperglycemia, hypertension, Cushing syndrome, immunosuppression, peptic ulcer disease, steroid-induced psychosis, and increased risk of tumor lysis syndrome.[1,149] If glucocorticoids are not effective, or if they are not tolerated, another option for lowering 1,25-dihydroxyvitamin D production is to use the P450 inhibitor, ketoconazole, which has been shown to reduce 1,25-dihydroxyvitamin D levels and hypercalcemia.[150]

Dialysis

Patients with hypercalcemia and acute kidney injury with oliguria may require dialysis to lower their calcium levels. In these patients, a saline diuresis is not possible and could lead to significant fluid overload. Hemodialysis or peritoneal dialysis using a very low calcium or calcium-free dialysate can be considered in such situations[127] and can result in a rapid decrease in serum total calcium levels.[151]

Other treatments

Gallium nitrate was initially evaluated as a cancer chemotherapeutic and was noted to cause hypocalcemia by inhibiting bone resorption.[152] It was given as a continuous intravenous infusion of 100 to 200 mg/m^2 of body surface area over a 24-hour period for 5 consecutive days.[1,127] Gallium nitrate can cause nephrotoxicity, and it is important that adequate urine output be maintained on this therapy.[153] In one study comparing treatment with gallium nitrate to calcitonin, 18 of 24 patients receiving gallium nitrate achieved normocalcemia, and the median duration of normocalcemia was 6 days.[153] In another study comparing gallium nitrate therapy to treatment with etidronate, 28 of 34 patients (82%) who received gallium nitrate achieved normocalcemia, and the median duration of normocalcemia was 8 days.[152] Gallium nitrate was withdrawn from the market in 1995 and discontinued by the manufacturer in 2012 in the United States.

Mithramycin, otherwise known as plicamycin, is an antibiotic agent that was initially used to treat testicular neoplasms and was found to lower serum calcium levels.[154] It was used for the treatment of hypercalcemia of malignancy before the introduction of bisphosphonates. It interferes with osteoclastic function and can reduce serum calcium levels within 24 hours.[155] It is given as a single dose of 25 mcg/kg of body weight over a 4- to 6-hour period in saline. Its side effects include thrombocytopenia, platelet defects resulting in bleeding diathesis, azotemia, proteinuria, and hepatic toxicity.[156] It is rarely, if ever, used currently.
